Abstract

This paper is an empirical study of what motivates net contributors to support redistributive policies. While studies in the area have tended to consider broad measures of inequality and support for redistribution in general, we focus on a single, salient relationship between local unemployment rates and demand for spending on unemployment benefits. Using a particularity of the Spanish labour market we estimate how workers’ stated preferences for unemployment benefits spending respond to changes in the local unemployment rate. We then decompose this response into the part explained by risk aversion, and thus demand for insurance, and the part explained by inequity aversion. Our results suggest that increases in local unemployment rates lead to increased demand by workers for unemployment benefits spending. Moreover, our results are consistent with an insurance motive driving this relationship but provide little support for inequity aversion. Our results suggest that studies of the relationship between inequality and demand for redistribution might benefit from considering both the source and measure of the inequality and the instrument of redistribution.

1 Introduction

One of the main roles of modern governments is the redistribution of income. There is a growing literature in Economics which seeks to understand just why it is that net contributors to a redistributive system support it (Boeri, Börsch-Supan and Tabellini, 2001). Nearly every OECD country has a degree of progressiveness in their income tax system (OECD, 2008, p. 112) designed to redistribute income from the better off to the worse off indicating a preference among the population for redistribution. Some of the research in this area has shown that the source of the inequality can play a role in determine the degree to which people support redistribution. However, much of the literature on redistributive preferences has focused on a general conception of these preferences and subsequent demand for redistribution. We consider redistributive preferences within the context of a single redistributive instrument: unemployment benefits.

In general, the specific policy instrument used to redress inequality has been ignored when studying people’s preferences for redistribution. But the policy instrument is an essential part of question of redistributive preferences. Piketty (1996) notes ‘individuals might well share the same ‘values’ as far as distributive justice is concerned, but...they disagree about the way actual inequality between individuals is generated.’ (p. 8). Where people disagree about the source of inequality, they will likely also disagree about the policy best suited to redress the inequality. It is therefore essential to consider redistributive preferences within the context of a particular instrument since the underlying reasons for why a person supports redistribution might vary from one instrument, say transfers to the poor, to another, say unemployment benefits.

In this paper, we examine the relationship between changes in the income distribution, as measured by changes to the unemployment rate, and stated preferences for unemployment benefits. Economists have identified a number of potential motivations underlying support for redistribution like demand for insurance and inequity aversion and Alesina and Giuliano (2009) note that the empirical disentanglement of these motives is difficult, albeit not ‘fatally’ so. We address this challenge directly and seek to contribute to the empirical work on redistributive preferences (e.g. Dahlberg, Edmark and Lundqvist, 2012; Luttmer and Singhal, 2011; Guillaud, 2013), using a newly constructed data set and a particularity of the Spanish labour market whereby public sector workers enjoy nearly inviolable job security. We estimate the effect of individual unemployment risk and of the local unemployment rate on workers’ declared prefer-
ences for redistribution via one instrument: unemployment benefits. We then decompose that effect into the part explained by risk aversion and demand for insurance and the part explained by inequity aversion. Our results suggest that in this case it is demand for insurance that drives declared preferences for redistribution. We find no evidence that inequity aversion plays a role in determining people's preferences for redistribution via unemployment benefits.

Studying the unemployment rate/benefits relationship may provide deeper insight into preferences for redistribution given the saliency of the two. Gimpelson and Treisman (2015) find that there are systematic differences between the perceived and actual level of income inequality when considering income shares. Kuzienko, Norton, Saez and Stantcheva (2013) argue that demand for general redistribution might not be too intense because people are unlikely to be aware of the level and changes in some more general inequality metric. Atkinson (2015) also raises the issue of the saliency of changes in income distributions. He notes that a change in the Gini of at least three percentage points may be necessary to be salient. Such a large change generally takes years if not decades to be realized, perhaps reducing the salience of the overall change. Ashok, Kuziemo and Washington (2016) use broad questions about redistributive preferences⁠¹ and inequality⁠² and find little evidence that rising inequality in the US has led to increased demand for redistribution over the past 40 years. It is arguable that the absence of any effect in their study is due to the in-salient nature of changes to measures like the Gini or percentile ratios. The level of unemployment, however, is a clearly visible, often reported and simple to comprehend variable making it more likely that individuals will recognise any change and respond, assuming that they respond at all. Moreover, in the case of unemployment, the instrument (unemployment benefits) and the target of the redistribution (the unemployed) are inextricably linked making it simpler to analyse the relationship between the two.

While focusing on unemployment goes some way towards addressing issues of salience, it does so at the cost of generality. Our results tell us something about the relationship between unemployment and demand for redistribution via unemployment benefits but may tell us little about how demand for redistribution via some other instrument will respond to changes in the income distribution. Nor are our findings on the underlying motives necessarily generalisable to other forms of redistribution. The unemployment rate/benefits nexus is distinct from more gen-

¹ Using, for example, the question from the US General Social Survey that asks respondents if they agree with the statement that “The government should guarantee basic standard of living”.
² They use changes in the income share of the top 1% of earners.
eral conceptions of redistribution in some important ways. Unemployment benefits are designed primarily to smooth consumption over time. Moreover, the insurance function of unemployment benefits is likely to be more salient than its redistributive function. Unemployment benefits are often referred to as unemployment insurance, though there is indeed a redistributive component to unemployment benefits. As Boadway and Oswald (1983) argue, ‘casual observation suggests that policy-makers have in mind redistribution of income as at least one rationale for unemployment insurance’ (p. 195). Moreover, the unemployment rate and broader measures of income inequality are linked (Bover, Bentolila and Arellano, 2002; Castells-Quintana and Royuela, 2012).

This lack of generality may be a feature of our setting as well as a short-coming. Disagreement over the manner in which income is redistributed is found in McCall and Kenworthy (2009) who show that while people object to increasing inequality and support government intervention to address the problem, they disagree about the appropriate instrument to do so. Thus, the relative importance of different motives underlying redistributive preferences may depend on the choice of redistributive instrument under consideration (Husted, 1990). General survey questions about the role of government in the redistribution of income may neglect heterogeneity of the preferences over the source of inequality and the instrument of redistribution and may therefore fail to measure the relationship of interest. Again, we pay a cost of ‘generality’, but gain an advantage insofar as our conclusions apply to a particular policy in a clear and direct way. In summary, using unemployment and unemployment benefits to study redistributive preferences allows us to focus on a single, salient measure of inequality and a specific, well-defined instrument through which it is redressed.

The rest of the paper is as follows. Section 2, we briefly review the literature and outline a theoretical framework to aid us in interpreting our results. In Section 3, we describe our data and discuss our identification strategy. Results are discussed in Section 4. Conclusions are drawn in Section 5.

2 Preferences for redistribution

Economists have identified different reasons why net contributors might support redistributive policies. First, demand for insurance may underlie preferences for redistribution. Net contributors may support redistributive polices in case they themselves become net recipients
at some point. This explanation fits comfortably with standard notions of economic self-interest and redistribution as insurance has been studied extensively by economists (Casamatta, Cremer and Pestieau 2000; Moene and Wallerstein, 2001; De Donder and Hindricks, 2003; Zweifel, 2013). However, demand for insurance is insufficient to fully describe preferences for redistribution (Fong, 2001).

Economists have therefore considered alternative explanations for redistributive preferences whereby net contributors derive utility from the welfare of others, directly or indirectly. People might derive utility from the welfare of others due to altruism (Rueda and Pontusson, 2010). Alternatively, people might display self-interest of the ‘enlightened’ variety, which would also require an ‘other-regarding’ component to preferences. Such ‘other-regarding’ preferences (Cooper and Kagel, 2013) would present themselves as a form of inequity aversion (Fehr and Schmidt, 1999), i.e. increased inequality would lead people to demand more redistribution. We remain agnostic about why people might be concerned with the welfare of others and focus instead on whether we see evidence of inequity aversion in preferences for redistribution via unemployment benefits. We therefore consider a inequity aversion motive in addition to the insurance (risk aversion) motive.

Our primary interest is in empirically estimating the responsiveness of declared preferences of workers for unemployment benefits spending to changes in the local unemployment rate. To aid in the interpretation of our results we outline a simple theoretical model. We assume a continuum of agents normalised to 1. Of these agents, share \((1 - u)\) will be employed and \(u\) will be unemployed and eligible for unemployment benefits where \(0 < u < 1\). We are interested in the preferences of the employed agents. All employed agents earn the same (gross) labour income, \(y\), and consume \(c_e = (1 - t)y\), where \(t\) is a payroll tax used to fund the unemployment benefits.

---

3 For example, Alesina and Giuliano (2009) note that ‘the level of inequality may affect crime and some people may be more or less subject to the risk of criminal activities’ (p. 1). So net contributors may be concerned with the level of inequality or the welfare of the poor but only insofar as it reduces the exposure of the contributor to crime.

4 Preferences may also have a fixed component. For example, individual beliefs have been shown to be important. Such beliefs likely exhibit a degree of persistence. For example, religious beliefs are found to be important (Neustadt, 2011) in the formation of redistributive preferences. An individual’s beliefs about potential socio-economic mobility (Piketty, 1995) and/or the relative roles of ‘luck’ and effort in determining outcomes (Fong, 2001) have also been shown to be predictive of that individual’s preferences for redistribution. While such beliefs can play a role in determining the level of demand for redistribution via unemployment benefits, our interest is in the responsiveness of this demand to changes in the level of unemployment, so any fixed component of preferences will drop out in the derivative. We therefore exclude fixed beliefs from our analysis and focus instead on the roles of risk and inequity aversion.
benefit system and $0 < t < 1$.\textsuperscript{5} Unemployed agents receive benefits, which allows them to consume $c_u = \beta y$, where $\beta$ is the replacement rate, $0 \leq \beta < (1 - t)$. That is, the effect of the choice variable, $t$, on the consumption of the unemployed is realised via $\beta$. Agent $i$ derives utility from her own consumption and we allow her to possibly derive utility from the consumption of unemployed people as well, where $\theta_i > 0$ captures the degree to which $i$ derives utility from $j$’s consumption.

The timing of the model is as follows. We impose a veil of ignorance (Rawls, 1971) on agents such that, \textit{ex ante}, they observe $x_i$, a vector of $i$’s employment characteristics (e.g. education, occupation, industry of employment and sector of employment), and know that share $u$ of all agents will be unemployed. The veil conceals the agents’ \textit{ex post} employment status, although each knows the probability that she will be unemployed, $p_i = p_i(x_i, u)$, where $\partial p_i/\partial u \geq 0$ and $\hat{p} = u$. \textit{Ex ante}, agents declare their preferred level of redistribution via unemployment benefits, $t^*_i$, given $x_i, u$ and thus $p_i$. While this set-up is highly artificial it provides an analogue to the situation where workers have a preferred level of benefits spending in the face of uncertainty about their continued employment and the prevailing level of unemployment.

The expected utility of agent $i$ is:

$$E[U_i] \equiv (1 - p_i)U(c^e_i) + p_iU(c^u_i) + \theta_i \hat{U}(c^j_u)$$ (1)

where there first term is the utility $i$ derives from her own consumption if she is employed, the second term is the utility $i$ derives from consumption if she is unemployed and the third term is the utility $i$ derives from the consumption of others when they are unemployed.

The budget constraint of the unemployment benefit system is:

$$ty(1 - u) = \beta y u$$ (2)

Rearranging yields

$$\frac{1 - u}{u} t = \beta$$ (3)

\textsuperscript{5} Until 2009, unemployment benefits were essentially fully funded out of social security contributions, but since then, due to the severity of the crisis and the high unemployment rate, those contributions fund about 50% of the unemployment benefit system. To make up the difference, the central government transfers resources - funded out of general taxes. For simplicity, though, we use a single tax to fund the unemployment benefits system in our model.
where $\partial c_u/\partial t > 0$ and $\partial c_u/\partial u < 0$. That is, $\beta$ varies with $t$ and $u$ to ensure the budget constraint holds with equality.

Substituting equation 3 into equation 1 and maximising it with respect to $t$ yield the FOC:

$$t^* = \frac{1-w}{u} \left[ p_i U'_u + \theta_i \tilde{U}'_u \right] = (1-p_i)U'_c$$

where primes stand for partial derivatives of a single variable; and assume utility is an increasing, concave function of consumption such that, $U''(.) < 0 < U'(.)$. We assume that the marginal utility from $i$'s own consumption when unemployed, $U'_u$, is at least as large as the marginal utility $i$ derives from $j$'s consumption when $j$ is unemployed, i.e. $U'_u \geq \tilde{U}'_u > 0$.

We then totally differentiate equation 4 with respect to $u$, and substitute the equation 4 into it, yielding:

$$\frac{dt^*_u}{du} = \frac{t^*_u}{u} \left\{ \frac{(1-u)\varepsilon_{p_i,u}' [U'_u + \theta_i \tilde{U}'_u] + p_i U'_u [RA_i - 1] + \theta_i \tilde{U}'_u [IA_i - 1]}{(1-u) [p_i U'_u RA + \theta_i \tilde{U}'_u IA]} \right\} \geq 0 \quad (5)$$

where $\varepsilon_{p_i,u}' \equiv \frac{\partial p_i}{\partial p_i} \geq 0$ is the sensitivity of $i$'s own probability of employment to changes in $u$, $RA = \frac{U''}{U'_u} > 0$ is a measure of relative ‘risk aversion’ à la Arrow-Pratt (Arrow, 1965) and, similarly, $IA \equiv -\frac{U''}{U'_u} c_i u > 0$ accounts for $i$‘s ‘inequality aversion’ (Atkinson, 1970). Note that the sign of equation 5 is unambiguously non-negative when $IA > 1$ and $RA > 1$ (Meyer and Meyer, 2005).

The first two terms in the numerator $\left\{ (1-u)\varepsilon_{p_i,u}' [U'_u + \theta_i \tilde{U}'_u] + p_i U'_u [RA_i - 1] \right\}$ capture the insurance motive. The more risk averse $i$ is, the greater her demand for insurance. The last term $(\theta_i \tilde{U}'_u [IA_i - 1])$ describes the inequity aversion component which is a function of both the degree to which $i$ is concerned with the welfare of others (i.e. other-regarding), $\theta_i$, and how averse they are to inequality, $IA_i$ (i.e., the larger the increase in $i$'s marginal utility from changes to $c_i$, again due to the binding budget constraint of the system).

Our interest is not in the determinants of the level $t^*$ but in estimating an analogue of

---

6 Changes in $\beta$ occur in practice as budget constraints becomes binding. For example, before July 2012 $\beta = 0.7$ in Spain. At that time the Spanish government enacted a law such that the replacement rate remained at 70% only for the first six months of being unemployed, but from then on decreased from 60% till 50% (up to a maximum of 24 months). This constituted a change in $\beta$ resulting from increased $u$ and falling tax revenue ($\beta$ remained constant). See http://www.fedeablogs.net/economia/?p=23617.

7 Note that fixed beliefs about the level of $t^*$ could be introduced here in the form of a constant on the left hand side, but, as noted above, we exclude fixed beliefs from the model for the sake of simplicity as their inclusion here would not change the predictions of the model we are interested in.
\( \frac{dt^*}{du} \), the responsiveness of \( t^* \) to changes in \( u \), and to disentangle the risk and inequity aversion components underlying the effect. Empirically, such disentanglement requires one of the motives to be held constant. The degree to which agents are other-regarding \( (\theta_i) \) is unobservable as is \( IA \). Our strategy therefore is to control for the risk of unemployment, \( p_i \), and thus the insurance motive (risk aversion) by exploiting an institutional feature of the Spanish labour market.

In Spain most public sector workers hold civil servant status. These workers, known as *funcionarios*, hold life-long appointments and are thus shielded from the vagaries of the labour market.\(^8\) This institutionalized job security can be used to hold the insurance motive for redistribution via unemployment benefits constant, as these workers face almost no risk of unemployment, i.e. \( p \approx 0 \) and \( \varepsilon_{p,u} \approx 0 \). Given this feature of the Spanish labour market, we consider two cases from the above framework:

**Case I: Private sector worker** \( (p_i > 0, \varepsilon^i_{p,u} > 0, \theta_i \geq 0) \)

These workers face a positive probability of becoming unemployed, \( p_i > 0 \) and this probability is a function of exogenous economic conditions, i.e. the unemployment rate, so \( \varepsilon^i_{p,u} > 0 \). As we cannot observe \( \theta_i \), if we estimated \( \frac{dt^*}{du}_{private} > 0 \), we would not be able to conclude anything about the underlying motives. As suggested above, to disentangle the motives we must hold one of them constant. We do this by considering the case of public sector workers.

**Case II: Public sector worker** \( (p_i \approx 0, \varepsilon^i_{p,u} \approx 0, \theta_i \geq 0) \)

These workers have little reason to demand redistribution as insurance as they enjoy a very high degree of, though not absolute, job security. Therefore, we would interpret a positive estimate of \( \frac{dt^*}{du} \), as evidence of inequity aversion, i.e. \( \theta_i > 0 \). Conversely, if \( \frac{dt^*}{du}_{public} = 0 \), it would be consistent with the absence of inequity aversion, \( \theta_i = 0 \), a conclusion that could be generalised to all workers under the restriction that \( \theta |_{public} \geq \theta |_{private} \). We discuss this restriction in greater detail below.

### 3 Data and estimation

#### 3.1 Data

We use survey and administrative data from Spain. Spain is an ideal setting for our study as unemployment benefits are homogenous across the country, labour mobility is low (Bentolila

---

\(^8\) Although *de jure* funcionarios can be fired for insufficient performance (article 63, of the Law 7/2007, April 12th, Basic Statute of the Public Worker), *de facto* this is extremely rare (Sanchez-Motos, 2007).
and Jimeno, 1998) and unemployment benefits are tied directly to a particular tax in the form of social security contributions. In Spain, Social Security contributions are collected from earned income and this revenue must be used to fund unemployment benefits. This direct link arguably makes the cost of increasing unemployment benefits more salient as it would require an increase in Social Security contributions.

Information on individuals’ declared preferences for public spending, including on unemployment benefits, as well as individual level socio-economic characteristics are taken from the 2005-2010 waves of the Centro de Investigaciones Sociológicas (CIS) survey. This annual survey in Spain is based on a nationally representative repeated cross section of 2,500 individuals and focuses on subjective perceptions of the tax system and publicly provided goods and services. Our interest is primarily in the stated preferences for spending on unemployment benefits by employed respondents, 50.4% of the full sample. Respondents who are retired, studying, unemployed or out of the labour force are excluded from the main analysis.

In addition to the socio-economic characteristics, we observe the municipality of residence for each individual in the sample. We add information at the municipal level including unemployment rates, population, mean income for municipalities with at least 1,000 residents covering 98% of the population (detailed data are not available for the smaller municipalities). We also add information on crimes at the provincial level as these are not available at the municipal level. These data are collected from La Caixa and from the Instituto Nacional de Estadística (INE) in Spain. Comparable data are not available for Navarra and Pais Vasco and so these Autonomous Communities (ACs) are excluded from the analysis. We are left with a sample of 5,741 workers residing in 1,139 municipalities over five years.

Table 1 presents descriptive statistics for worker-level and municipal-level variables by sector of employment. In Panel A we present the descriptive statistics for the workers and in Panel B we present these for the municipal-level data. In column (1) we present the means and standard deviations (in brackets) for private sector workers and in column (2) we present the same for public sector workers. Though we are unable to identify those with funcionario status, and thus virtually inviolable job security, most public sector workers are in fact funcionarios. During the observed period, the share of public workers who are ‘civil servants’ (funcionarios, in Spanish)

---

9 Spain has three levels on sub-national administration. There are 17 Autonomous Communities (analogous to US states) which nest 50 provinces (analogous to US counties) which nest 8,119 municipalities.
was about 60 percent.\footnote{See the 2013 data released by the Boletín Estadística del Personal al servicio de las Administraciones Públicas.} However, it is important to note as well that even those that do not have funcionario status (that is, their labor relationship with the public sector is through a temporary or private contract) enjoy a higher degree of job security than workers in the private sector (Sánchez-Motos, 2007). The final column shows the results of a t-test for the difference in the means with standard errors in brackets.

The first variable in Panel A of Table 1 (Prefers more UB) is our dependent variable. This dummy is based on a survey question on respondents' feeling about the current level of spending on unemployment benefits. The question allows for five possible (mutually exclusive) responses: ‘too much’, ‘too little’, ‘just the right amount’, ‘unsure’ and refusal to answer.\footnote{In Spanish, the survey question reads as follows: “Como Ud. sabe, el Estado destina el dinero que en España pagamos en impuestos a financiar los servicios públicos y prestaciones de las que venimos hablando. Dígame, por favor, si cree que el Estado dedica demasiados, los justos o muy pocos recursos a cada uno de los servicios que le voy a mencionar”. In English: “As you know, the state spends the money that we pay in taxes in Spain to finance public services and benefits about which we are speaking. Tell me, please, if you think the state spends too much, the right amount or too little on each of the services we will mention.” One of the several publicly provided goods and services that is asked about is unemployment benefits.} We have excluded those who are unsure or refuse to answer (16 percent of respondents).

We define our dependent variable as equal to 1 if the respondent says ‘too little’ is spent on unemployment benefits and 0 otherwise.\footnote{We use a binary dependent variable defined in this way for expositional expediency. We also estimate a multiple outcome model as a robustness check though.} We take it as given that this means that they would prefer more money to be spent on unemployment benefits. We assume that respondents are aware of the mechanism through which unemployment benefits are funded (note that respondents are prompted at the time of the survey that greater expenditure is funded via taxation), that is we assume that respondents know that there is no costless increase in public spending.

The second variable in Panel A, ‘unemployment risk’, is an estimate of each worker’s unemployment risk based on their labour market characteristics. It is, in effect, an estimate of a worker’s idiosyncratic risk of unemployment, $p_i$, defined in Section 2. We estimate $p_i$ using the sample of employed individuals (those in Table 1) plus the sample of individuals who are unemployed but previously had worked (i.e. those eligible for benefits or who left their job willfully, but not retired people or those out of the labour force). The CIS records the sector, occupation and industry for current jobs (if employed) and for previous jobs (if unemployed).
\[ p_i = w_i' \omega + \eta_i \]  \hspace{1cm} (6)

where \( p_i \) is a dummy variable equal to 1 if \( i \) is currently unemployed and 0 if \( i \) is employed, \( w \) is a vector of \( i \)'s employment characteristics including occupation\(^\text{13}\), industry of employment\(^\text{14}\) and level of education all interacted with the sector of employment and year effects, \( \omega \) is a vector of parameters to be estimated and \( \eta_i \) is a well-behaved error term. We estimate equation 6 via a probit and the predicted probabilities, \( \hat{p}_i \), constitute the ‘unemployment risk’ variable.

As can be seen in Table 1 \( \bar{p}|\text{public} = 0.06 \), about half figure for the private sector, meaning our estimate of unemployment risk is positive for public sector workers despite their relatively high degree of job security. With respect to Case II discussed at the end of Section 2, the data suggest that \( p_i \) is greater than 0, though closer to 0 than for those in the private sector. However, the data support the restriction that \( \epsilon_{p,u}^i \approx 0 \), as \( \bar{p}|\text{public} \) is not sensitive to changes in \( u \). Note that \( \bar{p}|\text{public} \) and \( \bar{p}|\text{private} \) are not the probabilities of transitioning to unemployment but are an unemployment rate. As such \( \bar{p} \) over-estimates the probability of transitioning to unemployment in a given period since we only observe the stock of unemployed people, not the flow (we do not know when they became unemployed). The important feature for our purposes is that \( \bar{p}|\text{public} \) does not vary over time and \( \bar{p}|\text{private} \) does. If \( \bar{p} \) is increasing over time it suggests that an increasing number of people are transitioning to unemployment. If it is stable over time it suggest the probability of transitioning to unemployment has not changed. Figure 1 plots \( \bar{p}|\text{public} \) and \( \bar{p}|\text{private} \) as well as the national unemployment rate.

As the economy fell into recession and unemployment rose, \( \bar{p}|\text{private} \) increased (positive changes each year) meaning the probability of a private sector worker transitioning to unemployment most likely increased as well. In the public sector \( \bar{p}|\text{public} \) changes very little meaning the risk of transitioning to unemployment remains stable over the period i.e. \( \epsilon_{p,u} \approx 0 \). Official employment statistics tell a similar story.\(^\text{15}\) Between 2008 and 2010, private sector employment fell 11 percent, from 18.1 million to 16.1 million whereas public sector employment actually grew

\(^{13}\) Based on the 1979 National Classification of Occupations
\(^{14}\) Based on the two-digit National Classification of Economic Activities.
\(^{15}\) Employment numbers were obtained from the INE.
slightly from 2.5 million to 2.6 million.\(^\text{16,17}\)

As for the other individual-level characteristics (Panel A, Table 1), public sector workers are three years older on average, less likely to be male and more likely to be a household’s primary earner. Public sector workers tend to be more educated. Public sector workers are also more likely to identify themselves as left-leaning politically.

In Panel B of Table 1 we consider the characteristics of the municipalities where the public and private sector workers reside. The first variable in Panel B is the municipal unemployment rate, our regressor of interest. On average, private sector workers live in municipalities with slightly lower (half a percentage point) rates of unemployment. Otherwise public and private sector workers do not live in systematically different municipalities, at least as measured by the characteristics presented here. Note that no measure of individual or household income, shown to be important determinant of redistributive preferences (e.g. Alesina and Giuliano, 2009), is reported in the CIS, so we use mean municipal income, obtained from tax records, as a proxy for household income (more on this below).

### 3.2 Estimation

Our analysis aims to determine the degree to which changes in the municipal unemployment rate drive changes in stated preferences for spending on unemployment benefits, other things being equal. To do so, we specify the following model of stated preferences for redistribution via unemployment benefits:

\[
d_{ikt} = x'_{ikt}\beta_1 + \pi_i x'_{ikt}\beta_1 + m'_{ikt}\beta_2 + \pi_i m'_{ikt}\beta_2 + \\
+ \beta_3 u_{kt} + \beta_3 \pi_i u_{kt} + \beta_4 \pi_i + \epsilon_{ikt} \tag{7}
\]

where \(d_{ikt}\) is a dummy for worker \(i\) in municipality \(k\) at time \(t\) which equals 1 if that worker believes ‘too little’ is spent on unemployment benefits, \(\pi_i\) is a dummy equal to 1 if \(i\) is employed

\(\text{16}\) We have also considered an alternative approach to identifying the funcionarios by assuming that funcionarios are over 30 years of age, working in the public sector administration and working in one of four occupations which we assumed to be most likely assigned funcionario status (no official mapping exists). The mean ‘unemployment risk’ for this arbitrarily defined group is indeed lower (0.04 versus 0.06 for all public sector workers taken together) and it also does not change over time.

\(\text{17}\) Over this same period there was a corresponding increase in the number of unemployed people in Spain increased from 2.6 million to 5.0 million. This strengthens our argument that \(\hat{p}\), while not measuring the actual probability of transitioning to unemployment, is in fact consistent with, if not indicative of, the probability of transitioning from employment to unemployment. And that increase in \(\hat{p}\) will thus be indicative of increases in the probability of transitioning to unemployment. Note that it is also true that higher values of \(\hat{p}\) can result from increased unemployment duration. So, more generally \(\hat{p}\) can be considered at the very least informative about individual exposure to the risk and duration of potential unemployment.
in the public sector, $x_{ikt}$ is a vector of worker characteristics including age, gender, estimated 'unemployment risk' ($\hat{p}_i$), a dummy for the presence of children in the household, marital status and a series of dummies controlling for home ownership distinguishing between a homeowner with no mortgage, a homeowner with partially paid mortgage, a renter and a residual 'other' category to help control for workers’ mobility (discussed further below). $\beta_1$ is the corresponding vector of coefficients to be estimated, $m_{kt}$ is a vector of municipality $k$’s characteristics at time $t$ including log population, the log number of foreign residents, as there is evidence to suggest that ethnic fractionalisation can affect redistributive preferences (Dahlberg et al. 2012) and the log mean income to help control for income as we do not observe individual level income (discussed further below). We also include the log number of crimes, though at the provincial level. $\beta_2$ is the corresponding vector of coefficients to be estimated, $u_{kt}$ is the unemployment rate in municipality $k$ at time $t$, $\beta_3$ is the impact of the local unemployment rate on stated preferences for unemployment benefits where $\beta_3$ is an analogue of $\frac{\partial u^*}{\partial u}$ and $e_{ikt}$ is a composite error term with a fixed component, $\alpha_i$, and a random component, $\zeta_{ikt}$. Note that given this fully interacted specification $\beta^\text{Private}_j = \beta_j (j = 1, 2, 3)$ is interpreted as the effect for private sector workers and $\beta^\text{Public}_j = \beta_j + \beta_{j\pi}$ as the effect for public sector workers. A formal test of whether the effect differs for the two groups is a simple $t$-test of $H_0 : \beta_{j\pi} = 0$.

The dependent variable is binary and thus we might estimate equation 7 using a non-linear limited dependent variable estimator such as a probit. Such estimators, however, require additional assumptions for consistency (eg homoskedasticity, see Greene (2012), pp. 692-693) over and above those of OLS. We therefore estimate equation 7 as a linear probability model (via OLS) which can produce consistent estimates of the marginal effects in which we are interested (Angist and Pischke, 2009). We do check the robustness of our results to the use of a probit below.

Regardless of the estimator used, estimation of equation 7 and the interpretation of the results is complicated by four factors: the presence of fixed effects, possible geographical sorting by workers, potential omitted variable bias caused by unobserved income at the individual level and possible sorting into sectors on unobservables. First, there may be systematic regional differences in redistributive preferences. For example, regional social norms have been found to be important in the formation of redistributive preferences (Kuhn, 2011). If these norms vary across regions, then we must control for them. To do so we include AC fixed effects. We
also include year fixed effects to control common shocks affecting the Spanish economy. This aids the identification of the effect of the unemployment rate rather than the effect of general macroeconomic changes that would correlate with the local unemployment rate.

A second issue is that workers may sort themselves geographically according to their level of human capital. Those with larger endowments of human capital are more mobile than others (Stambøl, 2003) and may migrate towards the areas with better job opportunities, i.e. lower unemployment, such that the correlation between the level of human capital and local unemployment rates could be negative. Such individuals, those with more education for example, have generally been found to prefer less redistribution (Alesina and Giuliano, 2009) so $\frac{\partial \text{redistribution}}{\partial \text{human capital}} < 0$. As a result, OLS estimates of $\beta_3$ may be positively biased. However, while such sorting may be a concern in theory, we note above that internal labour mobility in Spain is in fact very low (Bentolila and Jimeno, 1998) so it is less likely to be a problem in our setting.

Even so, we include the homeownership status of individuals as a regressor the argument being that homeowners are less mobile and thus are less likely to have migrated for work. We also estimate the model using only workers who own their own homes as a robustness check.

Third, a further bias may result from the fact that we do not observe $i$’s income. Income is a key variable in determining demand for redistribution in Meltzer–Richard model (Meltzer and Richard, 1981), though empirical results have been mixed. Some find little evidence of income forming redistributive preferences (Fong, 2001; Corneo and Grüner, 2002) while others (Alesina and Giuliano, 2009) find that it is important. By the Meltzer–Richard model, we expect $\frac{\partial \text{redistribution}}{\partial \text{income}} < 0$, i.e. higher income earners will tend to prefer less redistribution. We further expect a negative correlation between individual income and local unemployment rate, as higher rates of unemployment will exert downward pressure on wages (Blanchflower and Oswald, 1994). Therefore OLS estimates of $\beta_3$ may be positively biased. We attempt to mitigate this bias by including the mean income in each municipality, though within municipality variation will clearly still remain. We further control for a number of individual characteristics correlated with income and potentially redistributive preferences (age, education, gender, occupation, and industry of employment) though the omission of individual income will negatively bias the coefficient on ‘unemployment risk’.

Lastly, differences between public and private sector workers could complicate the interpretation of our results. We adopt an estimation strategy where employment in the public sector
might be conceived of as the ‘treatment’ and our interest is in whether the treatment changes how the unemployment rate affects stated redistributive preferences. However, this ‘treatment’ is, of course, not randomly assigned. Selection into one sector or another will be the function of any number of factors, many of which will be unobservable. Therefore, we cannot consider the sector of employment as a random, or even as a conditionally random, ‘treatment’. This selection into sectors will be problematic if workers sort into those sectors based on relevant un-observable characteristics such as the degree to which they are ‘pro-social’ or ‘other regarding’ (\(\theta\)). Such selection will limit any claims we might make about causality, but it may not render the qualitative conclusions we draw from the sign and significance of results. As we are not able to model selection into the sectors explicitly for lack of an identifying instrument, we must then carefully consider the direction of the potential selection biases.

The existing evidence on the relative the magnitudes of \(\theta\) for public and private sector workers is mixed. Some studies have found public sector workers to be more pro-social/other-regarding (larger \(\theta\)) than private sector workers (Houston, 2000; Banuri and Keefer, 2013) which seems consistent with greater concern for redistribution, i.e. \(\theta_{\text{Public}} > \theta_{\text{Private}}\). Tonin and Vlassopoulos (2014), however, find no difference in pro-sociality between sectors, i.e. \(\theta_{\text{Public}} = \theta_{\text{Private}}\). We have no direct measure of \(\theta\) in our data, though public sector workers are more likely to self-identify as politically left-leaning, the end of the political spectrum traditionally associated with greater support for redistribution (Alesina and Giuliano, 2009). We are not aware of any study providing evidence consistent with \(\theta_{\text{Public}} < \theta_{\text{Private}}\).

Given the existing evidence, we assume \(\theta_{\text{Public}} \geq \theta_{\text{Private}}\) so that selection into the public sector produces a positive bias in estimates of \(\beta_{3\text{public}}\) and selection into the private sector produces a negative bias in estimates of \(\beta_{3\text{private}}\). Thus our estimates of \(\beta_{3\text{public}}\) can be seen as an upper bound and of \(\beta_{3\text{private}}\) as a lower bound.

4 Results

We present our main results in Table 2, estimating the model using employed individuals. All estimates presented in Table 2 are obtained via OLS and standard errors are clustered at the municipal level. In column (1) we present the results obtained from estimating the model for all workers while interacting all the regressors with a dummy equal to 1 if \(i\) is employed in the public sector in period \(t\) (see equation 7). We return to columns (2) and (3) in Section 4.1
below.

The marginal effect (calculated at the mean characteristics) of being in the public sector is -0.05 (p-value=0.013), indicating that public sector workers are, on average and \textit{ceteris paribus}, about 6 percentage points less likely to support increase unemployment benefits spending than their private sector counterparts.\footnote{Note that this marginal effect is complicated by the fact that the sector of employment also appears in the estimation of $\hat{p}$ in equation (6). The overall marginal effect of a being in the public sector is equal to $\frac{\partial \hat{d}}{\partial \hat{p}} + \frac{\partial \hat{d}}{\partial \hat{p}}$. Combining these yields an overall effect of being in the public sector -0.06. However, we are unable to compute standard errors for this effect as $\frac{\partial \hat{d}}{\partial \hat{p}}$ and $\frac{\partial \hat{d}}{\partial \hat{p}}$ come from different models using different regressors and different samples (employed and unemployed versus only the employed, respectively). As such we cannot obtain estimates of the standard error of the linear combination of the effects. Given this lack of standard error and as the full and partial effects are very similar, we report the partial effect in the tables of results.}

The coefficient on ‘unemployment risk’ ($\beta = 0.75$, $p - value < 0.000$) indicates that private sector workers facing greater ‘unemployment risk’ are more likely to support increased spending on unemployment benefits. The coefficient on the interaction term of public sector worker and ‘unemployment risk’ is negative ($\beta = -0.60$) and statistically significant, though only at the 10 percent level ($p - value = 0.073$), indicating that the effect of risk differs for public and private sector workers. The effect of this risk for public sector workers is close to zero ($\beta = 0.75 + (-0.60) = 0.15$) and not statistically significant ($p - value = 0.622$).\footnote{Results are unaffected by using the alternatively identified \textit{funcionarios} (see fn 16) instead of all public sector workers.}

Similar variation over public and private sector workers is present in the effect of the local unemployment rate. The effect is positive ($\beta = 1.28$) and statistically significant ($p - value = 0.002$) for private sector workers. This suggests that increases in the unemployment rate lead to increases in a private sector worker’s support for more spending on unemployment benefits. The interaction of the unemployment rate and the public sector is also significantly different from 0 ($p$-value=0.034) indicating that there is a significant difference in the effect between private and public sector workers. For public sector workers, the effect ($\beta = 1.28 + (-1.63) = -0.35$) is not statistically different from 0 ($p - value = 0.621$). These results suggest that while increases in the local unemployment rate lead those working in the private sector to prefer increased spending on unemployment benefits, the stated preferences of those enjoying the relative job security of the public sector do not change.

We summarise our main results graphically in Figure 2 which shows the marginal effects...
outlined above. The dark bars are the marginal effects for those working in the private sector, both of which are statistically different from 0 at the 5 percent level. The light bars are the marginal effects for those in the public sector, neither of which are statistically different from 0. Our main result suggests that changes in the local unemployment rate do affect the stated preferences for spending on unemployment benefits, but only for private sector workers, i.e. those workers with an insurance motive. In the absence of this motive, i.e. for public sector workers, changes in the local unemployment rate do not affect stated preference for redistribution via unemployment benefits.

We test the robustness of these results in a number of ways and present the results from these checks in Table 3. In column (1) we re-estimate the fully interactive model but include provincial rather than AC fixed effects. The effect of the unemployment rate and the difference in the effect for public and private sector workers maintains. The effect of unemployment rates on the stated preferences of public sector workers is not statistically different from zero.

Given the importance of the ‘unemployment risk’ variable in our model, we consider the robustness of the result to an alternatively obtained $\hat{p}_i$. We re-estimate equation 6 using a fuller set of regressors including gender, age and province of residence in addition to the labour market characteristics used in the initial estimation of ‘unemployment risk’. We use this new estimate of $\hat{p}_i$ and re-estimate our baseline model (results in column (2)). This alternative approach to estimating the ‘unemployment risk’ produces qualitatively similar results to those in column (1) of Table 2.

In column (3) we estimate the model using homeowners only as this is the sub-population least likely to relocate and thus bias our results as discussed in Section 3.2. Again the results are stable. In column (4) we present the marginal effects from a probit estimator. The magnitude and significance of the effects are very close to those in Table 2. Results from a logit (not presented) were very similar to those in column (4).

In our primary analysis we use a binary dependent variable equal to one if the respondent believes ‘too little’ is spent on unemployment benefits. This is based on a survey question with multiple responses however. We therefore use a multinomial logit and allow for three responses: ‘too little’, ‘just right’ and ‘too much’. In columns (5) and (6) we present the

---

20 While there are more provinces, and thus the fixed effects will capture more of the variation in unemployment rates, provinces are purely geographical units and do not have any administrative role.
marginal effects obtained from the multinomial logit where the reference group is that spending on unemployment benefits is ‘just right’. The coefficients in column (5) are the effect of each variable on the probability of reporting ‘just right’ relative to reporting ‘too much’. Here the coefficient on the local unemployment rate is negative as higher rates of unemployment reduce the probability a respondent believes ‘too much’ is spent on unemployment benefits relative to reporting that unemployment benefits spending is ‘just right’. The effect for public sector workers \((\beta = -0.50 + (0.76) = 0.26)\) is not statistically different from zero \((p-value = 0.512)\). In column (7) the coefficients are the effect on the probability of believing ‘too little’ is spent relative to the unemployment benefits spending being ‘just right’. The results are again consistent with the unemployment rate increase demand for unemployment benefits spending by private sector workers and not affecting the stated preferences of public sector workers.

We also carry out ‘placebo tests’ as it may be the case that private sector workers generally favour increased public spending in an effort to stimulate economic growth and thus improve their job prospects and reduce the risk that they become unemployed. In this case the change in declared preferences for increased spending on unemployment benefits would not necessarily reflect an increase in the demand for insurance, but rather than increased demand for public spending in general. The CIS survey asks respondents for their view not only on unemployment benefits spending but also on a number of other public goods. We model preferences for spending on each of these. We generate a series of dummies which take a value of one if the respondent thinks ‘too little’ is spent on four other publicly provided goods/services: health, education, the justice system, policing and infrastructure. We then replace our primary dependent variable with these dummies and re-estimate the model, excluding in each case respondents who refuse to answer as we do in the primary analysis. Results are presented in Table 4.

The impact of the unemployment rate and of ‘unemployment risk’ on stated preferences for the public provision of these other goods/services is insignificant at the 5 percent level in every case. The coefficients on the interaction terms for public sector workers and unemployment risk is significant at the 10 percent level for health care spending (column 1) as is the coefficient on the interaction term for public sector workers and the unemployment rate for Education spending (column 2). However, in neither case is the total effect for public sector workers found to be statistically different from 0. These results suggest that we are measuring a particular relationship between the unemployment rate and stated preferences for unemployment benefits
and not a more general relationship between the state of the economy and preferences for public expenditure.

We next extend the analysis allowing the effect of changes in the local unemployment rate varies not just between the public and private sector workers but more generally with the degree of ‘unemployment’ risk.

Our primary analysis exploits a peculiarity of the Spanish labour market whereby many public sector workers enjoy virtually inviolable job security. But some private sector workers may also enjoy a high degree of job security. The argument put forth in the Section 2 can be applied to private sector workers with a high degree of job security. That is, we can relax the dichotomy assumed until now (that public sector workers have job security and private sector workers do not) and allow the job security to vary over individuals. To do so we allow the effect of the local unemployment rate to vary with the individual ‘unemployment risk’ faced by an individual. We expect the stated preferences for unemployment spending of those workers facing higher levels of ‘unemployment risk’ will be more responsive to changes in the local unemployment rate.

To test this we include a further regressor which is the interaction of the municipal unemployment rate and \( \hat{p}_i \) from equation 6 and, additionally, the sector of employment. Results are presented in the last columns (2) and (3) of Table 2. In column (2) we include an additional interaction between the ‘unemployment risk’ variable and the municipal unemployment rate. The coefficient on this new interaction term is positive and statistically significant (\( p-value = 0.030 \)) suggesting that the impact of the unemployment rate on demand for unemployment benefits spending is larger for those workers at greater risk of losing their jobs.

This model, however, may be overly restrictive in that it forces the interaction of ‘unemployment risk’ and the local unemployment rate to be the same for public and private sector workers. To relax this we introduce a further interaction between the local unemployment rate, ‘unemployment risk’ and the dummy for public sector workers in column (3). The coefficients on the interaction terms are both statistically significant at the 10 percent level. At the mean ‘unemployment risk’ for private sector workers (\( \bar{p} = 0.123 \)), the effect of local unemployment for private sector workers is statistically significant 0.97 (\( p-value = 0.006 \)) and is increasing in ‘unemployment risk’. For public sector workers, however, the effect of the local unemployment rate (calculated at the mean of ‘unemployment risk’ for public sector workers, \( \bar{r} = 0.061 \)) is 0.11
and is not statistically different from zero ($p$-value $= 0.808$).

The stated redistributive preferences of those private sector workers in industries and occupations with less job security are more sensitive to changes in the local unemployment rate than those with more secure jobs. Such variation is not present for public sector workers since, even those workers in relatively less secure industries and occupations, enjoy the relative security of being in the public sector. This result reinforces the implications of the primary analysis and is consistent with the theoretical framework outlined in Section 2.

5 Conclusion

The redistribution of wealth is one of the primary activities of the public sector, controversial though it may be. The reasons why people demand such redistribution even when they are net payers into the system are not fully understood. Studying redistributive preferences with respect to particular instrument (unemployment benefits in this case) rather than in general might lead to more refined understanding of how those preferences are formed and expressed. In this paper we have set out to test the motivations underlying individuals’ stated preferences for one form of redistribution, unemployment benefits, and explore the extent to which support for redistribution is due to inequity aversion or risk aversion (demand for insurance). To do so we use data on workers in Spain, a country with an institution of near inviolable job security for public sector workers.

We have shown that changes in the local rate of unemployment have a significant and economically relevant effect on workers’ stated preferences for spending on unemployment benefits. We attempt to empirically disentangle the roles of demand for insurance and inequity aversion in forming preferences for redistribution. We find support for an insurance motive but no evidence of inequity aversion. From an economic point of view, it is important to know whether individual preferences for redistribution via unemployment benefits incorporate inequity aversion as well as risk aversion as failure to account for such motives may lead to an ‘under-provision’ of redistribution. The absence of evidence for inequity aversion has implications for the conception of redistribution, via this particular instrument, as a public good (Pauly, 1973; Dorsch and Graham, 2009). Therefore the identification of the motive underlying redistributive preferences is more than an academic exercise but can have policy implications as well.

It is important to note that while the results are consistent with the dominance of the insur-
ance motive in determining preferences for redistribution via unemployment benefits, we cannot
readily generalise to all redistributive instruments. It may be true that individuals view unem-
ployment benefits as a type of insurance while the purely redistributive role of those benefits
goes under-appreciated by workers. Our results do not mean that all forms of redistribution
are viewed as equal and that inequity aversion does not drive demand for other forms of redis-
tribution (e.g. food stamps, progressive income tax, social housing). The evidence presented
here suggests the absence of inequity aversion underlying demand for redistribution via unem-
ployment benefits. However, others have found evidence of inequity aversion, in some form,
underlying demand for redistribution in general (e.g. Corneo and Grüner, 2002). We hope our
result motivates future work focusing on the formation of redistributive preferences with re-
spect to particular redistributive instruments rather than preferences for redistribution in some
general sense to gain deeper insight into the complex nature of redistributive preferences.

Notes: The dependent variable in the main equation is a dummy equal to 1 if the respondent believes ‘too little’ is spent on unemployment benefits and 0 otherwise. Bootstrapped standard errors (in brackets) are clustered at the provincial level. Stars indicate statistical significance according to the following schedule: *** 1%, ** 5% and * 10%. Individual controls, municipal level controls and both year and AC fixed effects are included in all models.
Figure 2: The marginal effects of ‘unemployment risk’ and the unemployment rate for private and public sector workers

Notes: The left most bar is the estimated marginal effect of a change in the unemployment rate on support for increased unemployment benefits by private sector workers. The dark bars differ from 0 at the 5 percent level, light colored bars do not differ from 0 at even the 10 percent level.

</table>

Note: The dependent variable is a dummy equal to 1 if the respondent believes ‘too little’ is spent on each publicly provided good/service, in turn, and 0 otherwise. Bootstrapped standard errors (in brackets) are clustered at the provincial level. Stars indicate statistical significance according to the following schedule: *** 1%, ** 5% and * 10%. Individual controls, municipal level controls and year fixed effects are included in all models.

</tbody>
</table>

Note: The number of observations varies as we condition inclusion in these models on being included in the sample used in our primary estimation in Table 2 to ensure we are starting with the same base sample and then exclude those who are unsure or refuse to answer in each case. The dependent variable is a dummy equal to 1 if the respondent believes ‘too little’ is spent on each publicly provided good/service, in turn, and 0 otherwise. Bootstrapped standard errors (in brackets) are clustered at the provincial level. Stars indicate statistical significance according to the following schedule: *** 1%, ** 5% and * 10%. Individual controls, municipal level controls and both year and AC fixed effects are included in all models.
