Abstract

Intrauterine growth restriction is one of the most common obstetric conditions, affecting 7-10% of fetuses. Affected fetuses are actually exposed in utero to an adverse environment during the highly critical time of development and may face life-long health consequences such as increased cardiovascular risk in adulthood. Already in utero, fetuses affected by growth restriction show remodeled hearts with signs of systolic and diastolic dysfunction. Cardiovascular remodeling persist into postnatal life, from the neonatal period to adolescence, suggesting a primary fetal cardiac programming that might explain the increased cardiovascular risk later in life. In this review we summarize the current evidence on fetal cardiovascular programming in fetuses affected by growth restriction, its consequences later and possible strategies from which they could benefit to reduce their cardiovascular risk.
Introduction

Growth and development are ongoing processes that begin at conception and continue through the remainder of our lives. However, the majority of changes occur during the prenatal period, and any interference with these early and complex processes could have consequences later in life. Fetal growth depends on several factors, such as genetics, maternal predisposition, placental state, nutrition and oxygenation: if anything is abnormal, the growth of the fetus might diverge resulting in abnormal growth and organs remodeling. This phenomenon has been called *fetal programming*: an adaptive response to an adverse environment in the fetal life that can cause structural, functional and metabolic changes that can persist into postnatal life increasing susceptibility to adult diseases\(^1\).

For many years cardiovascular diseases (CVD) in adulthood were thought to be determined only by genetic factors and postnatal lifestyle of individuals; however, there is now growing evidence suggesting that in most cases, CVD is triggered in early stages of life and then undergo long subclinical phase that can last decades before the first clinical symptoms appear. Already in the early 90s, the group of David Barker in Southampton, UK, established a strong and independent association between low birth weight and CVD in adulthood, including hypertension and cardiovascular mortality\(^2\). Thereafter, a large number of epidemiological and animal studies confirmed a direct link between prenatal environment and CVD in adult life, raising the concept of fetal programming\(^3\): the complex interaction between genetics and environments in prenatal and early postnatal life, is determinant for the growth and development of the fetus and it defines the susceptibility to several disorders of adulthood, such as hypertension, diabetes, dyslipidemia. During prenatal life, cell proliferation and differentiation are very sensitive to any change harmful to the environment that can lead to permanent structural and functional alterations, which then may persist into the adult life. In relation to CVDs, fetal programming depends on metabolic and
cardiovascular programming. Metabolic programming was the traditional hypothesis to explain the association between CVDs and low birth weight diseases\textsuperscript{1,2}: nutrients restriction during a period of intense epigenetic programming would promote developmental pathways that suit this environment, but as in postnatal life nutrient available will be normal, this programing will lead to a higher incidence of metabolic diseases (obesity, diabetes mellitus, metabolic syndrome), which are known risk factors for CVD. However, in the last years there is a growing evidence of direct changes in the cardiovascular system that lead to a primary cardiovascular programming\textsuperscript{4}.

This review presents an overview of the cardiovascular programming originated in prenatal life when fetal growth is hampered, including its later consequences in adulthood and the possible window of early preventive opportunities.

**Intrauterine growth restriction**

*Definition and etiology*

Intrauterine growth restriction (IUGR) is defined as the failure to achieve the fetal endorsed growth potential and it affects 7-10\% of all pregnancies\textsuperscript{5}. Fetuses affected by IUGR have a 5- to 10-folds higher risk of dying in uterus, a higher risk of perinatal morbidity, and are also at higher risk of long-term impairments, including suboptimal cognitive development and postnatal cardiovascular defects\textsuperscript{1}.

Several causes have been shown to favor IUGR including smoking, maternal malnutrition, antiphospholipid syndrome, teratogen exposure, infections, genetic/structural disorders, and above all placental insufficiency, revealed by Doppler abnormalities during prenatal life. Placental insufficiency leads to fetal undernutrition, hypoxia and also pressure/volume overload of the fetal cardiovascular system. However, our knowledge of the spectrum of IUGR continues to evolve and
the current vision is that it is a multi-phenotypic disease mainly governed by the complex interactions between genes and environment.

Different terms have been used to define a small fetus: small-for-gestational-age (SGA) and IUGR for example, have often been used interchangeably, but not all small babies are growth restricted. Obstetricians generally refer to SGA to define a constitutional small fetus, whereas IUGR usually refer to a fetus with signs of restriction, such as a very severe smallness or any Doppler abnormality.

Classification of IUGR

Several classifications are used for IUGR, but there are two major main phenotypes according to the severity restriction. Early-onset IUGR are fetuses with a very severe restriction, usually caused by placental insufficiency. It affects less than 1% of pregnancies and it is commonly associated with preeclampsia. The severity of the condition generally requires iatrogenic premature delivery (<37 weeks) aimed at preventing intrauterine mortality and preserving maternal health.

On the other hand, in late-onset IUGR the degree of placental insufficiency is milder that reflects a less severity of restriction, allowing fetuses to be delivered near term. However, this group has also been associated with poorer perinatal outcome and long-term consequences.

Fetal cardiovascular programming

The primary function of the heart is to provide adequate perfusion of organs; if an insult arises, the heart adapts with changes in its structure and function in order to keep its primary duty. In the initial phase of an insult, the heart undergoes a long subclinical period of dysfunction with changes in its shape, size and function and this process is called cardiac remodeling. The intrauterine
environment of IUGR characterized by a state of chronic hypoxia and undernutrition, together with increased placental vascular resistance, results in a combined pressure and volume overload of the fetal heart, which induces abnormal cardiac function and a remodeling of its structure. Cardiac remodeling and dysfunction are thus present in IUGR fetuses as pathophysiologic mechanisms aimed at adapting to the adverse environment due to placental insufficiency. The remodeling should revert when the insult is removed, but the problem here is that it happens in prenatal life, in a very critical phase of development, when the organs are being programmed, which results that the remodeling could later persist even after the insult disappears\(^3\) underlying the fetal programming process.

**Fetal cardiovascular remodeling and dysfunction in IUGR**

Cardiac remodeling and dysfunction in IUGR fetuses is mostly subclinical and requires sensitive method for identification\(^3\).

Several different patterns of cardiovascular remodeling in IUGR fetuses have been described, depending on the severity of the condition and including specific structural changes of the fetal heart for most cases\(^7\). In placental insufficiency’s condition, reduced oxygen and nutrients may directly affect cardiomyocytes, and at the same time the increased placental resistance to blood flow leads to an increase cardiac afterload. Consequently, the fetal heart at the beginning develops a more spherical shape to reduce wall stress and better tolerate pressure overload. In other words, the fetal heart remodels, changing to a more globular shape to better cope with the increased afterload but becomes less efficient (Figure 1). However, if the insult continues and it is also more severe, increased sphericity may not be enough: the heart becomes *hypertrophic* to increase contractility and decrease local wall stress. This typically occurs for the most severe cases
(early-onset IUGR). To note, volume overload would also explain the cardiomegaly and mild pericardial effusion in this severe IUGR cases.

This profound remodeling is inevitably also associated with modifications of the cardiac function. While ejection fraction is habitually preserved until very late stages of deterioration, this occurs with a reduction in stroke volume and a concomitant compensating increase in heart rate in order to maintain cardiac output and the adequate perfusion to organs\textsuperscript{8}. Accordingly, myocardial imaging techniques have permitted to demonstrate a decrease in longitudinal motion (decreased annular displacement by M-mode), and impaired relaxation. Recently, data from 2D speckle tracking imaging has also demonstrated signs of pressure overload as the presence of post-systolic shortening in the basal septal part in half of the early-onset IUGR cases\textsuperscript{9} (figure 1, D).

Cardiovascular biomarkers in cord-blood also confirmed the cardiac dysfunction of early-onset IUGR fetuses: B-type natriuretic peptide, that is a gold standard marker of heart failure, and plasmatic troponin and heart-fatty acids-binding protein have been both reported to be increased\textsuperscript{10}. Moreover, increased cord blood levels of troponins and B–type natriuretic peptide have also been detected in some late-onset IUGR and SGA newborns\textsuperscript{10} without apparent signs of severity\textsuperscript{11}.

Cardiac ultrastructural changes in IUGR

Experimental evidence suggests that IUGR is not only associated with heart shape remodeling and dysfunction, but also with profound changes in the ultrastructure of the organ. Hearts from animal models of IUGR showed more prominent and dilated coronary arteries together with a decrease in longitudinal fibers compensated by a higher proportion of circumferential fibers\textsuperscript{12}. The number of cardiomyocytes was also reduced exhibiting more hypertrophic cells and altered spatial arrangement of intracellular energetic units\textsuperscript{12}. The contractility machinery seemed also be altered
with shorter sarcomere length and decreased levels of sarcomeric proteins tyrosin and myosin heavy chain. These data illustrate the profound change of the fetal heart architecture at organ, cellular and organelle levels being consistent with the postnatal persistence of cardiac remodeling induced in prenatal life.

**Persistence of cardiac remodeling in IUGR children**

Cardiovascular remodeling does not end in fetal life, but persists postnatally, in line with the current vision of primary fetal cardiovascular programming. Echocardiography in IUGR neonates reveals similar changes, such as more globular and less efficient hearts with reduced longitudinal motion and impaired relaxation.8 Several studies demonstrated significant cardiac changes in IUGR neonates.13,14 In a cohort of newborns, Sehgal et al. described the strain (deformation from the original state) and strain rate (rate of deformation) and reported a significantly lower global deformation in SGA neonates, that reveal how the heart adapts to chronically elevated afterload by hypertrophy.14 In another cohort of 80 SGA children and 80 controls followed from fetal life up to 6 months of age, the same cardiovascular changes observed in the prenatal period, mainly due to a more globular cardiac shape, dilated atria, thicker myocardial walls, remained essentially unchanged at 6 months of age; these SGA newborns had also an increased mean blood pressure (BP) and aortic increased intima-media thickness (IMT). This evidence actually confirm that changes occurring during fetal life do not promptly regress after birth. Most importantly, Crispi et al.4 reported in a cohort of 80 IUGR and 120 controls evaluated at 5 years of age, more globular shape of the hearts in those children born IUGR, a reduced stroke volume and subclinical longitudinal systolic and diastolic dysfunction. Additionally, IUGR children had a higher BP and carotid IMT. All these
previous studies support the notion that there is a direct cardiac programming in IUGR that is a main determinant of permanent postnatal cardiac and vascular differences in affected children. 

Vascular modifications in infants with IUGR are first described by Skilton et al.\textsuperscript{16}: they reported a higher aortic IMT in term infants with IUGR compared to controls. The aortic or carotid IMT are good non-invasive markers of pre-clinical atherosclerosis and may serve as sensitive markers of hypertension in young IUGR children; along with cardiac remodeling, vascular impairments may also have deleterious end-organ effects\textsuperscript{8}.

**Persistence of cardiac remodeling in IUGR adolescents and adults**

Evidence of how cardiovascular remodeling persists into later stages of life is still controversial\textsuperscript{17}. Sarvari et al.\textsuperscript{18} recently reported in a cohort of preadolescents (8-12 years) similar findings as those observed in previous children cohorts: patients with a past history of IUGR have different cardiac shape with more spherical and smaller hearts, a decreased longitudinal motion and deformation and impaired relaxation. A Swedish cohort also showed smaller ventricular and vascular dimensions with preserved function in 19 young adults born with severe IUGR\textsuperscript{19}. The Young Finns Study reported at an average of 31 years higher systolic BP, IMT, triglycerides and low density lipoprotein cholesterol in those born SGA\textsuperscript{20}. However, in the most recent follow-up evaluation (34-49 years), there were subtle differences in heart size and lower left stroke volume, but with normal sphericity indices, diastolic function and BP in adults born SGA at term\textsuperscript{21}. Similarly, The Enigma study, a long-term follow-up study of 882 young adults in UK, reported a small increase in systolic BP and central pulse pressure in those adults born SGA, but this association disappeared after adjustment for body size\textsuperscript{22}. The interpretation of these studies is challenging, as multiple influences have to be taken into account during the life of these individuals and there are limitations in the accuracy of obstetric information. Future studies are
warranted to document the dynamics of cardiovascular remodeling in adults and to better understand the link with CVD.

The “second hit” theory and a window of opportunity

Intrauterine growth restriction induces cardiovascular remodeling and programming, and individuals born IUGR should be considered at risk of CVD later in life. However, as life progresses, multiple factors seem to intervene, which as a whole could attenuate or increase the differences observed in IUGR both in utero and during early life. Whether and how other factors that intervene later in life interact with this predisposition to evolve to clinical CVD, remains a subject of research. The “second hit” hypothesis, well known in human oncology, supposes that a predisposition to a condition requires a second insult to manifest as clinical disorder. This hypothesis postulates that the cardiovascular remodeling in IUGR fetuses (first hit) confers a predisposition to CVD which needs to be combined with other stressors (second hit) to evolve to a clinical condition (Figure 2). This suggests that fetal programming could be improved or further worsened, depending on other exposures during life.

Children born IUGR may benefit from being followed to identify any sign of subclinical cardiac dysfunction and atherosclerosis; an excessive weight gain during infancy and early childhood, also known as catch-up growth\(^{23}\), should be discouraged, because it is a risk factor for later obesity and for elevated IMT. Furthermore, the early moments of life may be a unique window of opportunity (Figure 3): early interventions can have strong effects on the cardiovascular changes associated with IUGR. Observational and in-vivo studies demonstrate that breastfeeding\(^{24}\) and a high intake of dietary long-chain \(\omega-3\) fatty acids\(^{25}\) improve cardiovascular remodelling in children and adolescents born IUGR. The theoretical window of opportunity for preventing strategies spans
almost the entire life-course, but the impact of the first moments may be more relevant; preventive exposure to other risk factors, surveillance of catch-up growth, promotion of breastfeeding, healthy diet and physical activity are some of the interventions that could be recommended to this population to reduce the probability of CVD in life.

Conclusions

From a long-term perspective, IUGR probably represents the best paradigm of the impact of adverse environment during fetal life that has a consequence later in adulthood. Fetal cardiovascular remodeling in IUGR persist well into childhood and adolescence. Understanding the cardiovascular remodeling that occurs in IUGR might be useful in the monitoring and risk stratification and a more focussed intervention. Early-life preventive measures may have a strong impact in the future health of these children and merit to be carefully considered. Considering also the high prevalence of IUGR, intervention aimed at temper the detrimental effects of an altered fetal growth may have considerable effects also in terms of public health.
