(Received 2 August 2010; revised manuscript received 17 December 2010; published 27 May 2011)

The magnetic properties and pseudocritical behavior of ferromagnetic pure and metallic nanoparticles having concurrently atomic disorder, dilution, and competing interactions, are studied in the framework of an Ising model. We have used the free-energy variational principle based on the Bogoliubov inequality and Monte Carlo simulation. As a case of study for random diluted nanoparticles we have considered the Fe0.5Mn0.1Al0.4 alloy. It is characterized for exhibiting, under bulk conditions, low-temperature reentrant spin-glass (RSG) behavior. Besides, experimental and simulation results are available for that alloy. Our results allow to conclude that the variational model is successful in reproducing features of the particle size dependence of the ordering temperature for pure and random diluted nanoparticles. In this last case, low-temperature magnetization reduction was consistent with the same type of RSG behavior observed in bulk in accordance with the Almeida-Thouless line at low fields. A linear dependence of the freezing temperature with the reciprocal of the particle diameter was also obtained. Computation of the correlation length shift exponent for random diluted nanoparticles yielded the values $\nu = 0.926 \pm 0.004$ via Bogoliubov simulations and $\nu = 0.71 \pm 0.04$ via Monte Carlo simulations. Differences are attributed to the spin pair approximation used in the variational model. From both approaches, differences in the $\nu$ exponent of Fe0.5Mn0.1Al0.4 nanoparticles with respect to that of the pure Ising model agree with Harris and Fisher arguments.

I. INTRODUCTION

The magnetic properties of bulk metallic systems having concurrently atomic disorder, dilution, competing interactions, and characterized for exhibiting spin-glass (SG) behavior have been widely studied from different points of view: experiment, theory, and numerical simulation. Among the systems with such characteristics, we can mention, for instance, CuMn, FeAu, FeAl, FeNiMn, and FeMnAl (Refs. 11–15) alloys. These alloys are interesting due to the richness of magnetic phases that can be found, such as ferromagnetic, antiferromagnetic, superparamagnetic, cluster glass, SG, and reentrant SG (RSG) depending on stoichiometry, microstructure, degree of dilution, atomic disorder, magnetic field, and temperature. Typical Ising SG systems such as those based on FeMnTiO3, Fe(Cu,Al)Dy, LiHoYF, FeAl, and FeMnAl (Refs. 11, 12, and 15) are good candidates to study SG- and RSG-related properties through Ising-based theoretical models, where good agreement with experimental results has been achieved. In particular, pure SG and RSG behaviors, in ternary FeMnAl alloys, arise from several ingredients, including random atomic distribution of the alloy constituent elements in the crystalline structure, dilution provided by Al atoms giving rise to bond randomness, and, finally, competition among the different exchange integrals involved. On this last respect, competition, especially, is given by the difference in sign and magnitude of the $J_{Fe-Mn}$, $J_{Fe-Mn}$, and $J_{Mn-Mn}$ exchange integrals. For high enough iron contents, a RSG behavior within the ferromagnetic phase governed by the Fe matrix can arise. Up The to date, works reported on these kind of alloys deal with magnetic properties under bulk conditions. However, to the best of our knowledge, and despite all the literature related with the so-called surface SG-like behavior in nanoparticles, no studies on metallic nanoparticles having concurrently bond competition, magnetic dilution, and atomic disorder within the entire volume of the nanoparticles have been reported. This fact has led us to consider the interplay between these effects and those arising from finite size when considering nanoparticles having such ingredients. The purpose of this paper is to characterize from the magnetic standpoint how the SG behaviors found in systems such as FeMnAl alloys under bulk conditions become revealed in nanoparticles where the surface-to-volume ratio becomes increasingly important. Both the free-energy variational method based on the Bogoliubov inequality and a Metropolis Monte Carlo simulation in the framework of a nearest-neighbor Ising model were considered. The former has been already successfully employed as energy minimization tool in describing the magnetic properties of these kinds of systems where theoretical magnetic phase diagrams are in good agreement with the experimental ones. The layout of the paper is as follows. In Sec. II we describe the theoretical model and we emphasize the importance of a relationship for the average nearest-neighbor Ising model were considered. The former has been already successfully employed as energy minimization tool in describing the magnetic properties of these kinds of systems where theoretical magnetic phase diagrams are in good agreement with the experimental ones. The former has been already successfully employed as energy minimization tool in describing the magnetic properties of these kinds of systems where theoretical magnetic phase diagrams are in good agreement with the experimental ones.
II. THEORETICAL MODEL

Several features lead us to consider an Ising model: (i) Magnetic frustration can be better resolved with an Ising model than, for instance, with continuous spin models;1 it is in agreement with the framework we are interested in, which consists of iron-based nanoparticles with a very high effective magnetocrystalline anisotropy and where, despite having a cubic structure, a single easy axis can be experimentally induced;21–23 (iii) it has been already used in similar systems and quite good agreement with experimental data (magnetometric measurements and hyperfine fields from Mössbauer spectroscopy) has been achieved;7,11,12,15 and finally (iv) it allows to keep computational requirements under reasonable limits. Thus, our model is based on the following $N$ spin Ising Hamiltonian:

$$\mathcal{H} = -\sum_{\langle i,j \rangle} J_{ij} \sigma_i \sigma_j - h \sum_{i=1}^{N} \sigma_i. \quad (1)$$

The first sum runs over nearest neighbors $\langle i,j \rangle$, and $\sigma_i$ takes on the values $\pm 1$ or 0 depending on whether the $i$th site is occupied by a magnetic atom (Fe,Mn) or an aluminum one, respectively. The exchange integral $J_{ij}$ obeys the following probability distribution function accounting for disorder and the different couplings involved:12

$$P(J_{ij}) = p^2 \delta(J_{ij} - J_{Fe-Fe}) + 2p x \delta(J_{ij} - J_{Fe-Mn}) + x^2 \delta(J_{ij} - J_{Mn-Mn}) + (q^2 + 2xq + 2pq) \delta(J_{ij}), \quad (2)$$

where $p$, $x$, and $q$, with $p + x + q = 1$, are the fractional concentrations of Fe, Mn, and Al atoms, respectively. The terms $p^2$, $2px$, and $x^2$ are the probabilities of having nearest-neighbor Fe-Fe, Fe-Mn, and Mn-Mn bonds, respectively, interacting through the corresponding exchange integrals $J_{Fe-Fe}$, $J_{Fe-Mn}$, and $J_{Mn-Mn}$. Here, $J_{Fe-Fe}$, hereafter simply referred to as $J$, was set to 12.846 meV only for pure iron nanoparticles with body-centered cubic (bcc) structures, and was set to 16.872 meV for $Fe_0.5Mn_{0.1}Al_{0.4}$ nanoparticles having the same structure. These values reproduce the Curie temperatures of the corresponding systems under bulk conditions, and the difference among them is attributed to the presence of both Mn and Al atoms, and to the difference on the lattice parameters of Fe and $Fe_0.5Mn_{0.1}Al_{0.4}$.14 Additionally, for the alloy, the remaining exchange integrals were set to $J_{Fe-Mn} = -\alpha J$ and $J_{Mn-Mn} = -\lambda J$ with $\alpha = 0.005$ and $\lambda = 0.03$.12 They correspond to the so-called competitive parameters. In this work, such values are kept fixed regardless the size of the nanoparticles to be considered. The last coefficient $q^2 + 2xq + 2pq$ stands for diluted bonds, with $J_{ij} = 0$, corresponding to nearest-neighbor Al-Al, Al-Mn, and Al-Fe pairs. Finally, the second term in Eq. (1) is the Zeeman contribution dealing with the coupling of the spins with a uniform external applied magnetic field $h$.

Following the ideas proposed by Ferreira et al.,24 in the spin pair approximation, the system is considered as formed by $n_1$ single spins (S) and $n_2$ linked pairs (P) of spins with a total number of spins $N = n_1 + 2n_2$. Additionally, it is assumed that the magnetization can be obtained either from single spins or from spins belonging to a pair. Thus, the trial Hamiltonian can be written as

$$\mathcal{H}_0 = -\gamma_s \sum_{i \in S} \sigma_i - \sum_{j,k \in P} [J_{ik} \sigma_i \sigma_k + \gamma_p (\sigma_j + \sigma_k)], \quad (3)$$

where $\gamma_s$ and $\gamma_p$ are variational parameters, which can be interpreted as molecular fields to be determined from energy minimization conditions. Here, the first sum runs over single spins and the second one runs over pairs. Both Hamiltonians, Eqs. (1) and (3), can be related through the variational approach based on the Bogoliubov inequality:

$$[F] \leq [F_0] + \langle \mathcal{H} - \mathcal{H}_0 \rangle_0 \equiv [\Phi], \quad (4)$$

where $F$ is the Helmholtz free energy defined by $\mathcal{H}$, $F_0$ is the free energy defined by $\mathcal{H}_0$: $\langle \ldots \rangle_0$ refers to the thermal average in the ensemble defined by $\mathcal{H}_0$, whereas $\{ \ldots \}$ represents a configurational average in which atomic disorder is considered. According to the way as the system has been figured out, we have

$$F_0 = -k_B T \ln Z_0 = -k_B T \ln \left( Z_s^{-N} Z_p^n \right), \quad (5)$$

where

$$Z_s = 2 \cosh(\beta \gamma_s), \quad (6)$$

$$Z_p = 2 e^{\beta J_{ij}} \cosh(2 \beta \gamma_p) + 2 e^{-\beta J_{ij}}, \quad (7)$$

are the trial partition functions for single and pair spins, respectively. The configurational average of any observable $A$ is obtained from

$$\langle A \rangle = \int_{\{J_{ij}\}} A P(J_{ij}) dJ_{ij}. \quad (8)$$

Calculation of the quantities $[F_0]$, $\langle \mathcal{H} - \mathcal{H}_0 \rangle_0$, and $[\Phi]$, following the same procedure as it has been described in Refs. 12 and 24, leads to the following expression for energy minimization:

$$\frac{\partial \langle \Phi \rangle}{\partial m} = -2(n' - n_2)(p^2 - 2px - \lambda x^2) J m$$

$$-N h + (N - 2n_2) \gamma_s + 2n_2 \gamma_p = 0, \quad (9)$$

where $n'$ is the number of nearest neighbors, which depends on the crystalline structure, the type of boundary conditions, and the system size. Concerning the nanoparticles, we consider free boundary conditions. Since $\langle \Phi \rangle$ diminishes as $n_2$ increases, we take $n_2$ as large as physically possible, i.e., $n' = n_2$. Thus, the number of linked pairs is maximized. Hence we obtain the following relationship between the variational parameters or molecular fields $\gamma_s$ and $\gamma_p$:

$$\gamma_s = \frac{2 \gamma_p n'/N - h}{(2n'/N) - 1}. \quad (10)$$

Our system is a spherical nanoparticle composed of $N$ atoms arranged in a bcc structure with a core coordination number $z = 8$ and interatomic spacing $a$, which in the case of pure iron is $\sim 2.86 \text{ Å}$ whereas for $Fe_0.5Mn_{0.1}Al_{0.4}$ it is $\sim 2.96 \text{ Å}$.14 On the basis of such a representation and in order to get an expression for the maximum number of pairs divided by the total number of atoms, i.e., $n'/N$, or, analogously an effective coordination number $z_{eff} = 2n'/N$, we have simulated particles with bcc structure and different diameters $D$, in units of the lattice...
parameter $a$, and have counted the number of nearest-neighbor pairs. Figure 1 shows the size dependence of $z_{\text{eff}}$ from which the following relationship is fulfilled for $D \geq 3.4$:

$$z_{\text{eff}} = \frac{2n'}{N} = z - \frac{b}{D},$$

(11)

where $z = 8$ and the best fit yields $b = 10.13 \pm 0.04$ for a bcc lattice. In the case of a face-centered cubic (fcc) lattice, the following values must be used, $z = 12$ and $b = 12.65 \pm 0.06$. In principle, $z_{\text{eff}}$ can be interpreted as an effective coordination number for nanoparticles of diameter $D$ whose core coordination number is $z$.

Thus, the relationship between the molecular fields $\gamma_s$ and $\gamma_p$ can be rewritten as

$$\gamma_s = \frac{\gamma_p z_{\text{eff}} - h}{z_{\text{eff}} - 1}.$$  

(12)

Magnetization can be computed either from single spins or from spins linked to a pair, and it must be the same:

$$m = \frac{1}{\beta} \frac{\partial \ln Z_s}{\partial \gamma_s} = \frac{1}{2\beta} \frac{\partial \ln Z_p}{\partial \gamma_p}.$$  

(13)

After calculating the derivatives and performing the configurational averages using the bond probability distribution function given by Eq. (2), we obtain the following transcendental equation for the magnetization:

$$m = \tanh(\beta \gamma_s) = \sinh(2\beta \gamma_p) \left[ \frac{p^2}{\cosh(2\beta \gamma_p) + e^{-2\beta J}} + \frac{2px}{\cosh(2\beta \gamma_p) + e^{2\beta J}} + \frac{q^2 + 2pq + 2qx}{\cosh(2\beta \gamma_p) + e^{2\beta J}} \right].$$

(14)

Roots of this equation were obtained by using the FindRoot tool of MATHEMATICA. It must be stressed that such magnetization, according to the bond distribution function in Eq. (2), corresponds to an average magnetization per bond, whereas for the pure case ($p = 1$) becomes a magnetization per site. The presence of crossed terms involving the atomic concentrations of the constituent elements $p$, $x$, and $q$ in Eq. (14) reflects the average over all possible nearest-neighbors pairs as well as the random atomic distribution feature. Zero field magnetic susceptibility was obtained according to

$$\chi = \left( \frac{\partial m}{\partial h} \right)_0 = \frac{1}{\beta c} \left[ \frac{\beta \gamma_s}{\cosh(\beta \gamma_s)} \right]^{-1} = \left( \frac{\beta \gamma_p}{\cosh(\beta \gamma_p)} \right)^{-1} - 1.$$  

(15)

The calculation of the ordering temperature $T_c$ from Eq. (14), for which we impose $m = 0$, is performed by taking the limits $\gamma_p \rightarrow 0$ and $\gamma_s \rightarrow 0$. This yields the following expression for the magnetic phase diagram:

$$\frac{z_{\text{eff}}}{2(z_{\text{eff}} - 1)} = \frac{p^2}{1 + e^{-2\beta c J}} + \frac{2px}{1 + e^{2\beta c J}} + \frac{x^2}{1 + e^{2\beta c J}} + \frac{q^2 + 2pq + 2qx}{2}.$$  

(16)

Here, $\beta c = (k_B T_c)^{-1}$. We want to stress that such an ordering temperature is indeed a pseudocritical temperature as far as we are dealing with nanoparticles and susceptibility has a maximum and finite value at $T_c$.

III. RESULTS AND DISCUSSION

A. Coordination number

From the particle size dependence of $z_{\text{eff}}$ plotted in Fig. 1, particles with diameter $D = 10$ ($\sim 3$ nm) already exhibit an effective coordination number of $\sim 7$, which corresponds roughly to 88% of that of the bulk. Above $D = 10$, the effective coordination number resembles that of the system under bulk conditions. Below that value, the coordination number decreases rapidly and, therefore, strong modifications on the magnetic properties are expected to occur in this range, i.e., below $\sim 3$ nm. In order to gain a deeper insight on the interpretation of $z_{\text{eff}}$, we have computed the coordination number per particle $z$, by counting the number of nearest neighbors surrounding the atom at the i\textsuperscript{th} position, i.e., within the first coordination shell, and an average coordination number was computed according to

$$\langle z \rangle = \frac{1}{N} \sum_{i=1}^{N} n_i z_i.$$  

(17)
where \( n_i \) is the number of atoms having coordination number \( z_i \) (see Fig. 2). Hence, by comparing the results derived from Eqs. (11) and (17) in Fig. 1, we conclude that what we have called an effective coordination number can indeed be considered as an average coordination number, i.e., \( z_{\text{eff}} = \langle z \rangle \). For diameters below \( \sim 3.4\AA \) the average coordination number is characterized by jumps for which the discrete character of the system becomes more evident. A typical particle with \( D = 10 \) is illustrated in Fig. 2, where surface atoms with different coordinations are depicted with different colors. Our results are in agreement with those reported in metal Pt nanoparticles with different diameters where coordination numbers for the first through fifth coordination shells were obtained by extended x-ray absorption fine structure (EXAFS) spectroscopy.\(^{25}\)

### B. Pure nanoparticles

The particular case of pure ferromagnetic nanoparticles is easily obtained by setting \( p = 1, q = 0, \) and \( x = 0 \) in Eq. (16):

\[
k_g T_c(D) = \frac{2J}{\ln(z_{\text{eff}}/(z_{\text{eff}} - 2))},
\]

which gives the particle size dependence of the ordering temperature for nanoparticles with core coordination \( z \), diameter \( D \), and a nearest-neighbor exchange integral \( J \). These results are not exclusively applicable to pure \( \alpha \)-Fe nanoparticles and they can, in principle, employed for other pure ferromagnetic nanoparticles such as Ni or Co. We can also relate this ordering temperature with that of the system under bulk conditions\(^{12}\) in order to obtain a reduced ordering temperature,

\[
\frac{T_c(D)}{T_c(\infty)} = \frac{J(D) \ln(z/(z - 2))}{J(\infty) \ln(z_{\text{eff}}/(z_{\text{eff}} - 2))},
\]

where we have assumed that the exchange integral \( J = J(D) \) in the nanoparticle can be different from that under bulk conditions \( J(\infty) \). In a first order of approximation, and by assuming the same exchange integral value, which could be reasonable for high enough particle sizes, we have

\[
\frac{T_c(D)}{T_c(\infty)} \approx \frac{z_{\text{eff}}}{z},
\]

if we assume that no structural transition occurs as a consequence of size reduction. Otherwise, different core coordination numbers should be considered and the model is still applicable. Figure 3 shows the reduced ordering temperature for different diameters according to our model. A comparison between Eq. (19) for bcc \( (z = 8) \) and fcc \( (z = 12) \) lattice structures and the approximate expression given by Eq. (20) is included.

As it is observed, \( T_c \) decreases as the particle becomes smaller due basically to the decrease in the magnetic bond density. Therefore, the energy cost to carry out the transition is lower, and thus the ordering temperature is also smaller. As \( D \) increases \( T_c \) tends to its bulk value. Other models have been already proposed to understand the mechanisms lying on the effect of the breaking of exchange bonds upon the \( T_c(D) \) function for nanoparticles. On this respect, the following expression has been proposed:\(^{26}\)

\[
\frac{T_c(D)}{T_c(\infty)} = 1 - \frac{3\Delta L}{2D},
\]

where \( \Delta L \) is the thickness of a surface layer, and it has been considered as a parameter to characterize the deficiency in the number of exchange bonds for atoms at the surface region of a nanoparticle. However, this model cannot reproduce successfully experimental data of magnetite nanoparticles of different sizes with a constant \( \Delta L \), and hence it has been suggested that \( \Delta L \) should vary with the particle size, but such a dependence has not been yet established.\(^{26}\) Another model, based on the energy-equilibrium criterion between the spin-spin exchange interactions and the thermal vibration energy of atoms at the transition temperature and a size-dependent Debye temperature function, was developed in order to obtain both \( T_c(D) \) and \( T_N(D) \) of ferromagnetic and antiferromagnetic
nanocrystals. Such model yielded the following expression for nanoparticles:

\[
\frac{T_c(D)}{T_c(\infty)} = \exp \left[ -(\alpha - 1)/(D/D_0 - 1) \right],
\]

where \( \alpha \) is a measure of the root-mean-square (rms) thermal average amplitude of surface atom vibration relative to the core and \( D_0 \) denotes a critical size at which all atoms of the nanocrystal are located on its surface. Differently, our model contains just one adjustable parameter \( \alpha \). Concerning a comparison with experimental results, we want to stress that, in general, it is rather difficult to obtain a diameter dependence of the ordering temperature due to several factors such as shape inhomogeneities, size distribution, and, in some cases as Fe nanoparticles, surface oxidation.\(^29\) Despite of that, our results are, qualitatively, in good agreement with some others reported for nanostructures.\(^{27,29-31} \) In order to evaluate the reliability of our model, we have carried out a comparison with some experimental data available for Ni nanostructures.\(^{29,32} \) To do this, we have employed Eq. (19) with \( z = 12 \) corresponding to a fcc lattice according to the crystalline structure of Ni, \( T_c(\infty) = 631 \) K, a lattice parameter \( a = 3.52 \) Å, and we have also assumed that \( J = J(\infty) \). Results are shown in Fig. 4, where we have also included the results from the models cited above.

As observed, the agreement is rather good despite the simplicity of our model and without considering any adjustable free parameter. Discrepancies can be attributed to the fact that, first, we have considered a simple nearest-neighbor Ising model. Second, experimental data correspond to Ni nanostructures that are not spherical at all, whereas our model has been developed for spherical nanoparticles. Third, for real nanostructures, the average lattice parameter is certainly different from the bulk, mainly for very small particles of some few nanometers of diameter and, therefore, the exchange integral should undergo changes. Such changes can also be induced by other facts such as volume magnetostriction of Ni. Regarding a particle size dependence of an effective nearest-neighbor exchange coupling, it is interesting to notice that better agreement with experimental data can be achieved by proposing a simple dependence of the form

\[
J(D) = J(\infty)e^{\alpha/D}
\]

in Eq. (19). This proposal is based on the experimental fact that the lattice parameter of metallic nanoparticles contracts with decreasing particle size in such a way that the lattice parameter contraction \( (\Delta a/a) \) is an inverse function of the diameter of nanoparticles.\(^{25,33-36} \) Such a lattice contraction is attributed to a reduction of surface bond length as a response to surface stress. Contraction factors may vary with material and crystal orientation. It has been observed experimentally that the lattice parameter contracts by 2.4% in 5-nm Ni nanoparticles.\(^37\) On the other hand, fcc Ni is considered as a strong ferromagnet characterized by a less pronounced Ruderman–Kittel–Kasuya–Yoshida (RKKY) behavior, exponentially damped, and a faster decay of the exchange integral with the interatomic distance. More concretely, Ni remains ferromagnetic up to the fifth nearest neighbors, and within this range of distance the exchange integral is essentially a decreasing exponential function of interatomic spacing.\(^38,39\)

Concerning finite-size scaling (FSS) properties, Fig. 5 shows a log-log plot of the reduced temperature \( [T_c(\infty) - T_c(D)]/T_c(\infty) \) versus particle diameter \( D \), illustrating that the data obtained from Eq. (20) follow the FSS relation:\(^{40-44} \)

\[
\frac{T_c(\infty) - T_c(D)}{T_c(\infty)} = a D^{-1/\nu},
\]

from which our best estimate for the shift exponent associated to the correlation length is \( \nu = 1.0001 \pm 0.0001 \) for both bcc and fcc lattices. The observed exponent is slightly lower than the one reported experimentally for Ni nanostructures (\( \nu = 1.064 \)),\(^32\) and very similar to that of a two-dimensional (2D) Ising model (\( \nu = 1 \)) but much greater than the observed in the three-dimensional (3D) Ising model (\( \nu = 0.6289 \))\(^45\) and mean-field theory (\( \nu = 0.5 \)). Discrepancies are attributed to the so-called spin pair approximation in the variational approach, where the trial partition function is computed by dividing the system only in blocks of one and two spins. This ends up in a reduction of the degree of correlation and consequently in a change of the exponent value. Certainly, a more precise estimative of the partition function, and consequently of the magnetization and \( T_c \) can be achieved by considering the system as formed by higher-order blocks (four, six, eight spins, etc.).\(^32\) Even though such a calculation is tractable, it turns out to be heavy and very time consuming. This fact constitutes the main limitation of the variational model.

Regarding thermal properties, Fig. 6 shows the temperature dependence of the magnetization per site and the magnetic susceptibility for pure iron (\( x = 0, q = 0 \) and \( p = 1 \)) nanoparticles and for some selected diameters. Results for bulk iron are also included for comparison. A well-behaved thermal driven
ferromagnetic to paramagnetic phase transition is observed as well as the shift of the critical temperature to low values as the system size decreases. The location of the maximum susceptibility coincides with that derived from Eq. (18) and no divergences or singularities are observed.

C. FeMnAl nanoparticles

In the case of FeMnAl nanoparticles, we have chosen the stoichiometry \( \text{Fe}_{0.5}\text{Mn}_{0.1}\text{Al}_{0.4} \), which, under bulk conditions, has been studied by using Mössbauer spectroscopy and magnetometric techniques\(^{14}\) as well as from theory\(^{12}\) and Monte Carlo simulation.\(^{13}\) As it is known, the bulk alloy has a \( T_c \) close to room temperature (\( \approx 300 \text{ K} \)) in addition to the occurrence of a RSG behavior in the low-temperature regime. The pseudocritical line \( T_c(D) \) is given by Eq. (16), and the corresponding log-log plot is shown in Fig. 7. Data have been fitted using FSS theory [Eq. (24)]. Our best estimate for the correlation length shift exponent is \( \nu = 0.926 \pm 0.004 \). This exponent is still quite similar to that of a 2D Ising model, but slightly different from our previous exponent for the pure case. This feature is consistent with the Harris criterion\(^ {46-48}\) for which a different set of critical exponents may be expected for diluted and random systems having a distribution of competitive exchange integrals. In our case, dilution is provided by Al atoms and randomness is provided by the random distribution of the atomic elements in the alloy within the crystalline structure and over the entire volume of the nanoparticles. The exponent is also greater than the one computed via Monte Carlo simulation (\( \nu = 0.79 \pm 0.03 \)) of \( \text{Fe}_{0.5}\text{Mn}_{0.1}\text{Al}_{0.4} \) alloys under bulk conditions.\(^{13}\) In Fig. 8, we show the temperature dependence of magnetization per bond and magnetic susceptibility as obtained from Eqs. (14) and (15), respectively. As it is observed, our model predicts a magnetization reduction in the low-temperature regime, below \( \sim 70 \text{ K} \), in agreement with zero field cooling measurements for the bulk case.\(^{12}\) According to our model, such a reduction, which has been attributed to a RSG phenomenology within the ferromagnetic matrix, is still observed for nanoparticles. Moreover, the onset of the reentrant phase is supported by the low-temperature peaks of the magnetic susceptibility. Results reveal also the expected shift to lower-temperature values of \( T_c(D) \) as the particle size decreases, in agreement with the pseudocritical line obtained from Eq. (16).
FIG. 8. (Color online) Temperature dependence of magnetization per bond and magnetic susceptibility for Fe$_{0.5}$Mn$_{0.1}$Al$_{0.4}$ nanoparticles and for some selected particle sizes. Data corresponding to the bulk case are also included for comparison.

It is well established that Ising SG transitions should follow the so-called Almeida-Thouless (AT) line$^{49}$ from which it is expected a field dependence of the peak temperature ($T_p$), obtained from the maximum of the magnetization, of the form

$$h \propto (1 - T_p / T_f)^{3/2}.$$  \(25\)

The extrapolation of the AT line at $h = 0$ gives the freezing SG transition temperature $T_f$. Agreement of the data with the AT line is usually considered as evidence of the occurrence of a SG phase, although not concluding.$^{50}$ Thus, in order to evaluate the properties of the RSG phase, we have solved Eq. (14) for different low-field values in Eq. (12) from which $T_p$ was extracted with an uncertainty of $\pm 1$ K. Results are summarized in Fig. 9, where we plot $h^{2/3}$ vs $T_p$. Two remarkable features are observed in this figure. First, our data are in accordance with the AT line as one expects for a SG transition, at least at low-field values. The large plateau observed in the magnetization at

around $T_p$ has been already observed to occur experimentally from a superconducting quantum interference device (SQUID) and ac susceptibility measurements.$^{14}$ Additionally, for large field values, a deviation from the AT line was observed. These results are in agreement with those reported by Young$^{51}$ and references therein, where the difficulty of having an AT line for short-range Ising SGs at large fields was evident. In fact, the existence of a SG ordering in a magnetic field is still an open question.$^{52}$ Second, the freezing temperature is clearly size dependent, i.e., it diminishes as the particle size decreases. This fact implies that the SG region in the magnetic phase diagram becomes smaller for nanoparticles exhibiting SG behavior within their entire volume and not as a consequence of a merely surface effect as it has been proposed in nanoparticles exhibiting the so-called surface SG-like behavior. These results suggest that SG behavior observed in bulk systems is reduced when finite-size effects become important, which could be attributed to a reduction in the total number of frustrated spins as the particle size becomes smaller. Moreover, in the framework of the mean-field approximation, and taking into account that the low-temperature transition occurs within the ordered Fe ferromagnetic matrix, the particle size dependence of the freezing temperature can be understood by writing $T_f = z_{\text{eff}} J_{\text{Mn-Mn}} + z_{\text{eff}} p J_{\text{Fe-Mn}}$. This means that $T_f(D)$ should become proportional to $1/D$, according to Eq. (11). The inset in Fig. 9 reveals that such a trend is fulfilled.

FIG. 9. (Color online) Low-field AT line. The freezing temperature goes down as the particle size diminishes. The $T_f$ value for bulk at \(\sim 62.5\) K is relatively close to that reported experimentally at \(\sim 78\) K from ac susceptibility measurements for Fe$_{0.5}$Mn$_{0.1}$Al$_{0.4}$ bulk alloys (Ref. 14). The inset shows that a $T_f$ vs $1/D$ linear dependence is followed.
first $6 \times 10^4$ MCS for equilibration. Configurational averages over five different random atomic realizations were performed. We have also employed the same set of competitive parameters used in the variational approach and numerical values of $J_{Fe-Fe}$ (Ref. 54) reproducing the critical temperatures under bulk conditions. An example of the simulation results for a particle size $D = 10$ is shown in Fig. 10. In addition to the total magnetization per site, the corresponding Fe and Mn contributions are shown separately. Both approaches, variational and simulational, predict a low-temperature magnetization reduction. Monte Carlo results allow to conclude that such a reduction arises from Mn moments for which an increase in the absolute value of the corresponding magnetization contribution was observed. These moments tend to align antiparallel with respect to the total magnetization direction ruled by the iron matrix according to the negative values of $J_{Fe-Mn}$ and $J_{Mn-Mn}$. Moreover, such moments are not compensated and some of them are frustrated.

One of the difficulties of the variational approach is that the magnetization obtained in the random diluted case is a magnetization per effective bond and not per atomic site. This fact gives rise to different values of the maximum magnetization (see Fig. 8) in contrast to the observed via Monte Carlo simulation, where the maximum value of the overall magnetization is close to 0.5, in accordance with the Fe atomic concentration, which is practically the same, independent of the particle size. Finally, regarding the behavior along the $T_c$ line, we have determined the correlation length shift exponent from the maxima of the logarithmic derivative of the magnetization at the particle size dependence of the ordering temperature for both pure and random diluted particles. Comparisons estimate for the exponent was $\nu = 0.71 \pm 0.04$, very different from that found from the variational approach. Once more, the difference is attributed to the spin pair approximation used in the variational approach. Our value by the Monte Carlo simulation is, however, somewhat greater than the $\nu = 0.6289 \pm 0.0008$ value obtained by Ferrenberg and Landau for a 3D pure Ising model, where a high-resolution Monte Carlo study was carried out, and somewhat smaller than the $\nu = 0.79 \pm 0.03$ value obtained for the same system under bulk conditions. Differences respect to the $\nu$ exponent of the pure 3D Ising model can be attributed to the diluted character of our system, in addition to the disorder involved in the distribution of exchange integrals, which is consistent with Harris criterion, whereas the difference of the $\nu$ exponent of the nanoparticles with respect to the corresponding infinite system is consistent with Fisher’s theory.

IV. CONCLUSIONS

The pseudocritical behavior of ferromagnetic pure and random diluted nanoparticles with competing interactions has been addressed. In both cases we have employed the free-energy variational principle based on the Bogoliubov inequality and an Ising model. In the case of random diluted nanoparticles, for which we have considered the $Fe_{0.5}Mn_{0.1}Al_{0.4}$ system as a case of study, we have used, additionally, a standard Monte Carlo simulation. In order to validate the use of the variational approach in nanoparticles, the model was applied to account for the pseudocritical behavior of pure ferromagnetic nanoparticles on the basis of an average nearest-neighbor coordination number obtained via numerical simulation. Our results allow to conclude that the variational model is successful in reproducing features of the particle size dependence of the ordering temperature for both pure and random diluted particles. Comparisons
with other theoretical models and experimental results for Ni nanostructures were carried out in order to evaluate the reliability of the model. A better agreement with experimental data is obtained if a particle size dependence of the exchange integral is considered, consistent with previous works where lattice contraction of metallic nanoparticles has been observed.

For random diluted nanoparticles, low-temperature magnetization reduction was consistent with the same type of RSG behavior observed in the bulk counterparts, in accordance with the Almeida-Thouless line at low fields. Such a RSG behavior is attributed to the presence of competing interactions, randomness, and the aluminum dilution effect. A linear dependence is attributed to the presence of competing interactions, randomness, and the aluminum dilution effect. A linear dependence of the freezing temperature with the reciprocal of the particle size was also obtained, indicating that the corresponding change integral is considered, consistent with previous works where lattice contraction of metallic nanoparticles has been observed.

Differently from this, a value \( \nu = 0.71 \pm 0.04 \) was obtained via the Monte Carlo simulation. Differences are attributed to the so-called pair approximation in the variational approach.

From both approaches, differences in the \( \nu \) exponent of \( \text{Fe}_{0.5}\text{Mn}_{0.5}\text{Al}_{0.14} \) nanoparticles with respect to that of the pure Fe ising model agree with Harris and Fisher arguments. Finally, we want to stress that, even though thermodynamic models can be indeed used in the study of nanostructures and they can reproduce experimental features, special attention must be paid regarding pseudocritical behavior depending on the approximations of the model.
