## Abstract

The aim of this study is to identify dynamics of social learning between amphorae workshops during the Roman Empire. The Baetica province developed a massive infrastructure of olive oil production that supplied the Western provinces of Rome for almost 300 years. The olive oil produced in this area was shipped through maritime and riverine transport networks in a standardized amphoric shape made in several workshops spread around the region. These workshops have generated a large amount of evidence but it is still difficult to understand through archaeological proxies how the production of amphorae was organized.

We apply here an evolutionary framework to find links between workshops through the morphometric similarities of the amphorae they produced. The suggested approach identifies how individual potters acquired and transmitted technical skills by exploring small yet statistical significant differences in the amphorae made in 5 different workshops. Multivariate methods are used to cluster a variety of amphorae based on morphometric measurements and the outcome shows that the analysis is useful even when a high degree of standardization exists, such as was the case for Roman amphorae (i.e. Dressel 20).

Results suggest that morphometric similarity is inversely correlated with spatial distance between workshops. This pattern suggests that pottery-making techniques were transmitted through oblique transmission with little or no movement of potters between distant workshops. The conclusion is that morphometric similarity may be an effective proxy to identify social learning dynamics even amongst workshops producing exactly the same amphoric type.

## 1. Introduction

The archaeological record is useful to identify the mechanisms by which humans learn from each other (Richerson and Boyd, 2005; Eerkens and Lipo, 2007). The analysis of archaeological proxies able to capture variability can help us find traces of the social learning dynamics of the techniques used to make them (Shennan and Wilkinson, 2001; Eerkens and Lipo, 2005; Gandon et al., 2014). This approach has been successfully applied to the material culture generated by small-scale societies, but it has seldom been applied to large-scale standardized productions (Shennan et al., 2015).

This paper explores the social dynamics of specialized production in the Roman Empire. We focus here on analysing large-scale production of a single amphoric type (Dressel 20) in a specific area. An evolutionary framework is used to identify social learning dynamics between pottery-makers (Shennan, 2008a; Mesoudi, 2015).

Specifically, pottery making is learned through a variety of cultural transmission mechanisms depending on the organization of the community that made them (Neff, 1992; Shennan, 2002; Bowser and Patton, 2008; Hosfield, 2009). For example, vertical transmission is a mode of transmission where learning is transmitted from parents to offspring (similar to biological transmission); oblique transmission sees a master teaching a younger generation of disciples, whereas in horizontal transmission individuals of the same generation trans-

mit their knowledge to other individuals of the same generation (i.e. workers from different workshops) (Cavalli-Sforza and Feldman, 1981; Acerbi and Parisi, 2006).

25 All these methods require communication and for this reason the techniques to make artefacts such as pots and amphorae should vary across geographical distance (Björklund et al., 2010; Shennan et al., 2015; Van Strien et al., 2015). If vertical or oblique transmission are predominant then material culture should be similar in nearby groups with high intensities of interaction (Hart, 2012).  
30 The underlying consequence is that it should be possible to identify the degree of interaction between workshops by quantifying similarity amongst the amphorae they produced; if apprentices moved between distant workshops then no differences would be found on this proxy while oblique transmission would be revealed by distant workshops exhibiting less similarity.

35 These hypotheses on archaeological proxies of social learning have been tested elsewhere (Roux, 2015) and it has been shown that handmade pottery can be a good indicator of the different social learning mechanisms involved on the process (Neiman, 1995; Shennan and Wilkinson, 2001; Steele et al., 2010). However, cultural transmission on standardized productions such as the ones  
40 found during the Roman Empire has not been explored at the same level (Bevan, 2014).

The work we present here identifies learning processes of amphorae making in the case of the massive olive oil production organised during the Roman Empire. Olive oil was one of the most important products of the Classical Mediterranean  
45 world as it was used in almost all aspects of daily life including cooking, lighting and hygiene (Mattingly, 1988). The Baetica province (currently Andalusia, southern Spain) developed a massive infrastructure of olive oil production to face the demands of the Roman Empire. The product was shipped in large amounts of amphorae to distant provinces all along the Western provinces and  
50 specially to the city of Rome and the thousands of military garrisons deployed along the provinces in the border such as Britannia (Carreras Monfort, 1998; Funari, 2005) and Germania (Remesal, 1986).

Baetica was an important olive oil production and distribution centre for almost three centuries (Berni, 1998; Remesal, 1998; Chic, 2005; Remesal, 1977).  
55 The province had a strong connectivity through riverine transport that allowed inland producers to ship their products towards the trade networks through the Mediterranean and the Atlantic (García Vargas, 2010). The production of amphora shipping Baetican olive oil exhibits a sudden exponential increase as over a hundred of workshops were created to meet the volume of olive oil being  
60 produced. These workshops were located along the Guadalquivir river and its tributaries. The majority of amphorae produced in this area are classified as Dressel 20 type divided into a variety of subclasses (Martin-Kilcher, 1987; Berni, 2008).

Despite the abundance of Dressel 20 across thousands of archaeological sites,  
65 we still do not know how its production was organized. This challenge is common for all large-scale productions during the Roman Empire due to the lack of written records discussing the topic and the difficulties of identifying adequate archaeological proxies that give clues on the process. Several studies have analysed amphorae using a diversity of approaches, from chemical analyses to  
70 large-scale distribution (Isaksen, 2006; Brughmans and Poblome, 2016; Rubio-Campillo et al., 2017). However, the structure of social learning that transmitted knowledge on how amphorae were made is still poorly understood. Were these workshops run by families or groups of owners without kinship? Did apprentices work in the same workshop where they were trained? Did potters work in more  
75 than one workshop? Were changes in production decided by workshops or by external actors? All these questions are linked to the social learning processes that took place in the workshops. Additionally, archaeological record shows this specialized production was highly organized and homogeneous both in terms of products and processes. As a consequence, amphorae made in different work-  
80 shops do not exhibit a large degree of variations and they look identical: the same type of amphorae was produced over 300 years while similar stamps and information was recorded on them (Remesal, 2004).

We use here an evolutionary framework designed to improve our understand-

ing of these large-scale production dynamics. If the system was mainly driven  
85 by oblique transmission mechanisms then no potters would be moving to distant  
workshops. As a consequence, amphorae produced in nearby workshops might  
share more similar traits than with the rest of the production. On the other  
hand, if horizontal dynamics were common then this correlation with spatial  
coordinates should not be present as workers would share their methods across  
90 the entire study area.

The paper is structured as follows: the next section introduces the dataset  
and the methods used to analyse it. Section three presents the results while  
the last part discusses the outcomes and highlights the main conclusions of the  
work.

## 95 **2. Material and methods**

### *2.1. Workshops*

Our sample comprised 413 Dressel 20 amphorae collected from the five Dres-  
sel 20 workshops most intensively excavated during recent decades: Malpica,  
Cerro del Belén (hereafter, Belén) (Díaz Trujillo, 1992), Parlamento (García  
100 Vargas, 2000), Villaseca (García Vargas and Morena, forthcoming) and Las  
Delicias (Fernández et al., 2001; Mauné et al., 2014) (see their location in Fig-  
ure 1).

The sample was uniformly distributed as the 5 workshops provided a similar  
sample size (80-100 samples). These workshops were distributed in a diversity of  
105 locations therefore spatial dynamics could be potentially identified. All of them  
had a long time span of production; however, temporal variation was limited as  
the Dressel 20 type remained almost unchanged over three centuries (Berni and  
García Vargas, 2016). We analysed Dressel 20 of the three most abundant vari-  
ants in our dataset spanning approximately three centuries (Dressel C, Dressel  
110 D, Dressel E) (Martin-Kilcher, 1987; Berni, 2008). All the variants were found  
in the 5 workshops and, consequently, no intrinsic bias was generated by them.

Figure 1: The Baetica province during the Roman Empire. The location of the analysed workshops shows how Dressel 20 workshops were mostly distributed along the rivers Guadalquivir and Genil

## 2.2. Spatial Distance

The approach required us to compute a pairwise matrix of spatial distances between workshops. All these workshops were located near a river as the amphorae were shipped by boat after being made and filled with olive oil. Given  
115 the relevance of riverine transport, it was decided that the best proxy for spatial distance between workshops was the one observed following the river course, as summarized in Table 1.

<b>Workshops</b>	Malpica	Belén	Villaseca	Las Delicias	Parlamento
Malpica	-	11	50	17	108
Belén	11	-	33	29	98
Villaseca	50	33	-	67	133
Las Delicias	17	29	67	-	126
Parlamento	108	98	133	126	-

Table 1: River distance matrix between workshops (in km.)

## 2.3. Measurements

Eight different measurements were taken from each amphora. The metrics  
120 were focused on the rim sherds as this section was typically the best preserved in most archaeological contexts (Berni, 2008). Other interesting proxies such as handles and bases were found in lesser quantities and for this reason they would be less appropriate for quantitative approaches due to low sample size.  
125 The measurements used in this study are summarized in Figure 2; they were divided into exterior diameter, inside diameter, rim height, rim width, shape width, rim inside height, rim width 2 and protruding rim.

## 2.4. Exploratory Data Analysis

Principal Component Analysis (PCA) was used to explore the variation  
130 of the measurements over the different workshops (Jolliffe, 2002). PCA is a common method in archaeology in scenarios studying within-sample variation

Figure 2: The 8 morphometric measurements taken for all amphorae. A: External diameter. B: Inside diameter. C: Rim height. D: Rim width. E: Shape width. F: Rim inside height. G: Rim width 2. H: Protruding rim.

(Shennan, 2008b; Li et al., 2014; Schillinger et al., 2016b). The method allowed us to visualize the dataset by focusing on a small number of Principal Components (PCs) while retaining the variation required to identify differences  
135 between workshops.

### 2.5. Morphometric similarity

Exploratory Data Analysis was followed by the measurement of pairwise dissimilarity between the amphorae made in different workshops. The approach presented here is based on the following idea: if the amphorae made in two work-  
140 shops are difficult to distinguish then the workshops are making more similar artefacts. On the other hand, if the probability of distinguishing the production place of the combined dataset is high then there are remarkable morphometric differences between the artefacts made in different workshops. This goal was achieved by 1) train a clustering algorithm with the entire dataset, 2) use the  
145 trained model to predict the producer’s workshop and 3) calculate the confusion matrix between the workshops.

The clustering method used in the analysis was Linear Discriminant Analysis (LDA). The entire dataset was used both for the training and prediction steps as we were interested in identifying under what extent workshop attribution could  
150 be predicted relying exclusively on morphometric measures. A Confusion Matrix was then computed as the index of morphometric distance between amphorae of different workshops. The Confusion Matrix computes this quantity as the number of misclassifications between each pair of groups in the dataset (i.e. the workshops). This method has already been used in similar scenarios aiming  
155 at identifying differences in artefact production (Thorpe et al., 1984; Aguilera, 1998; Charlton et al., 2012). If the amphorae made in two workshops were easily confused then their average measures must be similar; on the other hand, if the rate of misclassification between two workshops is very low then the amphorae made in these locations are distinctively different.

160 The diagonal of the confusion matrix (i.e. correct classifications) was removed and the number of confusions per each workshop was then divided by

the total sample size. This value defined the percentage of errors from a given workshops related to the rest of the sample. The outcome was finally normalized to generate a pairwise distance matrix of morphometric measurements.

165 *2.6. Dissimilarity correlation*

The last step of this method was the comparison of the morphometric and spatial distance matrices. A significant correlation between these dissimilarity matrices would suggest isolation-by-distance, typically found if oblique transmission was the main social learning mechanism.

170 The evaluation of these two distance matrices (morphometric distance and spatial distance) was computed using a Mantel test. Mantel test evaluates the degree of pairwise correlation between two matrices and has been particularly useful in archaeology to explore the spatial dimension of cultural change (Mantel, 1967; Diniz-Filho et al., 2013; Crema et al., 2014).

175 **3. Results**

*3.1. Principal Component Analysis*

The loadings for the two main Principal Components of the dataset are listed in Table 2.

180 An exploratory visualization for these two main Principal Components can be seen in Figure 3. The plot suggests that each workshop exhibits slightly different dynamics for PC1 while PC2 is distinctively different for the two most distant sites (Villaseca and Parlamento). Additionally, the first PC also tends to display more similar values for amphorae made in nearby workshops such as Belén and Malpica. The exploratory analysis was also performed for different  
185 Dressel 20 types in order to observe possible patterns linked to their chronology. A similar pattern is observed in Figure 4. The result suggests a noticeable difference between Dressel C and Dressel D and E but barely perceptible between Dressel D and E.

Figure 3: Scatter and density plot for the First and Second PCs. Sample is split by workshop

Variables	PC1	PC2
Exterior diameter	0.877	0.312
Inside diameter	0.404	-0.887
Rim height	-	-
Rim width	0.149	0.119
Shape width	-	-
Rim inside	-	-
Rim width 2	0.133	0.142
Protruding rim	-0.159	-0.272

Table 2: Two main Principal Components. Diameter values and the protruding rim seem to capture the majority of variation.

Figure 4: Scatter plot for the First and Second PCs. Sample is divided by Dressel 20 types

### 3.2. Linear Discriminant Analysis

190 LDA’s prediction generated an overall accuracy of 56.6%. It is worth mentioning that we are not as interested in the overall accuracy of the clustering algorithm as we are on the distribution of these errors across workshops. This distribution can be seen in the Confusion Matrix of Table 3. Each row of the matrix represents the predicted class whereas each column represents the real  
 195 class. It can be observed that the most distant workshop (Parlamento) can be more easily predicted while the classification for the rest of the sample is less effective.

	Belén	Delicias	Malpica	Parlamento	Villaseca
Belén	48	11	16	4	6
Delicias	10	81	24	8	0
Malpica	12	12	49	1	6
Parlamento	6	10	9	25	10
Villaseca	12	5	13	4	31

Table 3: Confusion Matrix of errors in predicted classifications between workshops. The sample analysed gave an accuracy percentage of 56.6% with p-value <0.01.

A temptative glance to these results suggests that workshops with lesser spatial distance such as Malpica, Belén and Las Delicias made amphorae that  
 200 are more difficult to distinguish due to their similarity. By contrast, workshops as Parlamento shows a higher degree of misclassification that correlated with a higher spatial distance.

### 3.3. Mantel correlation test

The Mantel test applied to morphometric and spatial similarity generated a  
 205 correlation of 0.51 with p-value under 0.01. The analysis shows that morphometric distance of the amphorae are strongly correlated with the spatial distance of workshops. Closer workshops tend to be generate more similar amphorae than distant workshops. For example, Belén and Malpica are located at nearby positions and the morphometric distance seems more similar whereas Parlamento

210 displays significant differences with the rest of workshops. Thus, the results suggest that the variability on the making-techniques processes are related to spatial distance.

#### 4. Discussion and Concluding remarks

Similarity on the making techniques processes amongst workshops shows an  
215 inverse correlation with spatial distance. This phenomena can be explained by isolation-by-distance as mobility between workshops was limited. The similarity of morphometric traits of the analysed sample decreases with spatial distance, and as a result amphorae made in nearby workshops were more similar than amphorae made in distant workshops because contact between workers was less  
220 frequent.

Horizontal transmission nor high mobility seems to match with the results of the analysis. Scenarios with frequent contact between potters or workers moving from workshop to workshop would have generated larger homogeneity in the metrics. In addition, the morphological variability detected in differ-  
225 ent workshops also suggest that making-techniques were typically shared across workshops. No distinctive variation has been detected in the analysis and this outcome suggests that potters reproduced the same model of amphorae with a very slow rate of variation.

Oblique transmission could be the main social learning mechanism to explain  
230 the variability between these workshops. The equilibrium of this dynamic for a long timespan (over three centuries) can be interpreted as a high-fidelity social learning mechanism transmitted within each one of the workshops (Schillinger et al., 2016a). The disciples could have worked at the same workshop where they were trained and as a consequence individuals would have copied the model  
235 of amphora made by the previous generation within the same workshop. Small random errors would have been transmitted and amplified throughout the period when Dressel 20 were made and each workshop would have produced slightly different amphora assemblage. The large degree of standardization would have

minimized these differences but our framework is still able to identify them.

240 It is worth mentioning that the diversity of social learning processes involved  
in such a complex process is always high. The transmission of technical skills  
during apprenticeship (master to disciples) and their limited mobility does not  
imply that horizontal transmission did not exist. The process initially led by  
masters within the same workshop could be complemented by periods of high  
245 mobility of the workers linked to peaks of production.

To conclude, the method presented here provides a framework to identify  
social learning mechanisms using artefacts made in different sites. The method  
has proven valuable even in the case of the highly standardized amphoric pro-  
duction of the Roman Empire. The suggested method could also offer a good  
250 comparison with other analytical methods such as archaeometry; we believe that  
a framework integrating and comparing multiple sources of evidence could be  
extremely effective on the process of characterizing production sites and places  
of consumption. Our analysis provides a useful guideline for the exploration of  
the social learning processes connected to amphora production in the Roman  
255 Empire. Hence, the results have lightened to understand the link between social  
learning and archaeological evidence in a diversity of scenarios.
