24 **Abstract**

25 RATIONALE

26 The relationship between stocks of fin whales inhabiting the temperate eastern North
27 Atlantic and the Mediterranean Sea is subject to controversy. The use of chemical markers
28 facilitates an alternative insight into population structure and potential borders between
29 stocks because both areas present dissimilar isotopic baselines.

31 METHODS

32 Baleen plates, composed of inert tissue that keeps a permanent chronological record of the
33 isotopic value of body circulating fluids, were used to investigate connectivity and
34 boundaries between the stocks. Values were determined in a continuous flow isotope ratio
35 mass spectrometer (Flash 1112 IRMS Delta C Series EA; ThermoFinnigan, Bremen,
36 Germany).

38 RESULTS

39 Stable isotopes confirm that, while the two subpopulations generally forage in well
40 differentiated grounds, some individuals with characteristic Atlantic values do penetrate into
41 the Mediterranean Sea up to the northernmost latitudes of the region. As a consequence, the
42 border between the two putative subpopulations may be not as definite as previous acoustic
43 investigations suggested. The discriminant function obtained in this study may assist
44 researchers to use baleen plate isotopic data to assign the origin of fin whales of uncertain
45 provenance.

47 CONCLUSIONS

48 This study strengthens the stock subdivision currently accepted for management and
49 conservation while recognizes a low level of exchange between the Mediterranean and
50 temperate eastern North Atlantic subdivisions.

52 **Key words:** fin whale, stable isotopes, migration, management stock.

4
5
67 **54 Introduction**
8

9
10 55 Fin whales make wide-range movements and their migration typically spans thousands of
11
12 56 kilometres, traits that would in principle hinder the occurrence of demographic subdivisions
13
14 57 within a given ocean basin. However, in the North Atlantic Ocean fin whales have long been
15
16 58 known to actually subdivide into subpopulation units, with little individual interchange, and
17
18 59 which for management purposes are commonly denominated “stocks”. Jonsgård (1966)^[1]
20
21 60 was the first to comprehensibly investigate such structuring and, after considering the
22
23 61 apparent differences in the trajectory of the catch per unit effort of various localities where
24
25 62 the species had been exploited, the iodine values of the oil extracted from the captured
26
27 63 individuals and their mean body size, he inferred the existence in the basin of at least six
28
29 64 stocks. Later, evidence from further and more refined catch per unit effort series, differences
30
31 65 in age at sexual maturation and the results of marking programs, led the International
32
33 66 Whaling Commission (1977)^[2] to slightly modify Jonsgård’s proposal and to agree a
34
35 67 structuring of the North Atlantic into seven management subdivisions.

36
37
38 68 One of these subdivisions embraced the temperate waters of the eastern North Atlantic
39
40 69 comprised between the British Isles, France, the Iberian Peninsula and northern Africa up to
41
42 70 the 19°N line. Although marking with internal tags was conducted off NW Spain in the past,
43
44 71 all tags were recovered in the same whaling grounds and thus did not provide evidence for
45
46 72 stock structure. As a consequence, the rationale for that subdivision relied on a parallel
47
48 73 decline in catch per unit of effort observed by Jonsgård (1966)^[1] between the British Isles
49
50 74 and the Iberian Peninsula during the 1920s, a fact that was accepted as evidence of
51
52 75 connectivity between these areas. At that time, and despite absence of any supporting
53
54
55
56
57
58
59
60

1
2
3 76 evidence for connectivity, the fin whales inhabiting the Mediterranean Sea were
4
5 77 straightforward incorporated into the “British Isles-France-Iberian Peninsula-northern
6
7
8 78 Africa” stock. However, this was modified when later research showed that adult fin whales
9
10 79 and calves were present year round in the western Mediterranean^[3] and that individuals from
11
12 80 the Mediterranean Sea and the western North Atlantic differed both genetically ^[4,5] and in
13
14 81 their organochlorine pollutant concentrations and profiles^[6], intrinsic markers which are
15
16 82 frequently used to differentiate populations. The Mediterranean Sea was thus considered a
17
18 83 new subdivision, with the Gibraltar Straits as the border separating from the adjoining
19
20 84 Atlantic stock. Despite the persistence of some uncertainties about the actual subdivisions^[3],
21
22 85 this demographic structure has been adopted as the basis for management and conservation
23
24 86 by the International Whaling Commission^[7,8], ACCOBAMS^[9] and the International Union
25
26 87 for the Conservation of Nature^[10], among other organizations.
27
28
29 88 However, the genetic studies warned that the isolation between the Mediterranean Sea and
30
31 89 Atlantic stocks was not complete and estimated the exchange between them at about two
32
33 90 females per generation, without clarifying whether such exchange was unidirectional or
34
35 91 bidirectional^[5]. This appeared to be confirmed by satellite tagging, because from eight
36
37 92 whales successfully tagged in the north-western Mediterranean Sea one crossed the Straits of
38
39 93 Gibraltar towards the Atlantic and moved up to central Portugal^[11,12], and by acoustic
40
41 94 recordings that showed that whales producing songs attributable to the north-eastern North
42
43 95 Atlantic subpopulation were detected in the south-western Mediterranean Sea^[13]. However,
44
45 96 this last result does not demonstrate an actual exchange between Atlantic and Mediterranean
46
47 97 stocks, but just that the border between them is not the Straits of Gibraltar. Actually, whales
48
49 98 are observed every year crossing through the Straits of Gibraltar in both directions^[14,15] and
50
51
52
53
54
55
56
57
58
59
60

1
2
3 99 the prevalence of Atlantic immigrants into the south-western Mediterranean is also true for
4
5 100 other groups of marine vertebrates^[16,17].
6
7 101 Chemical markers may facilitate an alternative insight into population structure and potential
8
9 102 borders between stocks. In particular, stable isotope values in tissues are known to reflect the
10
11 103 environment in which individuals obtain their food^[18,19]. Here we use baleen plates, an inert
12
13 104 tissue that keeps a permanent chronological record of the isotopic value of body circulating
14
15 105 fluids^[18,20,21] to investigate connectivity and boundaries between the stocks inhabiting the
16
17 106 Mediterranean and the temperate waters of the eastern North Atlantic. The two areas present
18
19 107 dissimilar isotopic baselines, being $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ in the NW Iberian Peninsula higher than in
20
21 108 the Mediterranean Sea^[22-24], thus providing the necessary differentiation. The results will not
22
23 109 only be useful to gauge degree of exchange between putative subpopulations the main focus
24
25 110 of the present study, but would provide the basis for the assignment of origin to individual
26
27 111 whales in the future.

36 37 38 113 **Material and Methods**

39 40 41 114 *Sample collection and analysis*

42
43 115 The stable isotope data used for this research originated from two different sources: i) the
44
45 116 information provided by Bentaleb *et al.* (2011)^[12] from 10 baleen plates (BP1-BP10),
46
47 117 corresponding to 9 fin whales, stranded in the Mediterranean Sea during the period
48
49 118 1975-2002 (7 from northern-western basin and 2 from the south-western basin,), and ii) the
50
51 119 analysis of further baleen plates from five individuals caught off north-western Spain
52
53 120 (Caneliñas whaling station, identified as A-E, Figure 1), during the whaling season of 1985
54
55
56
57
58
59
60

1
2
3 121 (July to October). Because stable isotope values are known to fluctuate along the longitudinal
4
5 122 axis of the baleen plate following seasonal changes in area of residence and/or feeding
6
7 123 regimes^[18,20], in both cases each plate was subsampled at regular intervals along the
8
9
10 124 longitudinal axis to incorporate into the analysis the expected variation occurring throughout
11
12
13 125 the biological cycle.

14
15
16 126 For storage and analytical procedures (that were almost identical to those of the present study)
17
18 127 in the first set of baleen plates, see Bentaleb *et al.*, (2011)^[12]. In the case of the second set, the
19
20 128 baleen plates were stored dry until analysis. Before sampling, they were cleaned of surface
21
22
23 129 oils and adhered material using a steel palette knife, steel wool and a chloroform:methanol
24
25 130 solution (2:1), and subsequently subsampled with a micromilling device at 1 cm intervals,
26
27
28 131 including the unerupted section beneath the gum. Forty one subsamples were obtained from
29
30 132 each baleen plate. Approximately 0.3 mg of powdered baleen plate was weighed into tin
31
32 133 capsules (3.3 x 5 mm) and combusted at 1000 °C in a continuous flow isotope ratio mass
33
34 134 spectrometer (Flash 1112 IRMS Delta C Series EA; Thermo Finnigan, Bremen, Germany).
35
36
37 135 The analyses were performed at the *Centres Científics i Tecnològics* of the University of
38
39 136 Barcelona, Barcelona, Spain.

40
41
42 137 Stable isotope abundances, expressed in delta notation (δ), where the relative variations of
43
44 138 stable isotope values are expressed in permil (‰) deviations from the predefined
45
46
47 139 international standards, were calculated as:

48
49
50 140
$$\delta X = [(R_{\text{sample}}/R_{\text{standard}}) - 1] \times 1000$$

51
52 141
53
54 142 where X is ¹³C or ¹⁵N, and R_{sample} and R_{standard} are the ¹³C/¹²C and ¹⁵N/¹⁴N ratios in the sample
55
56 143 and standard, respectively. The standards were Vienna Pee Dee Belemnite (V-PDB) calcium
57
58
59
60

1
2
3 144 carbonate for carbon and atmospheric nitrogen (air) for nitrogen. International isotope
4
5 145 secondary standards of known $\delta^{13}\text{C}$ values from the International Atomic Energy Agency
6
7
8 146 (IAEA, Vienna), namely polyethylene (IAEA CH₇, $\delta^{13}\text{C} = -31.8\text{‰}$), graphite (USGS24, $\delta^{13}\text{C}$
9
10 147 = -16.1‰) and sucrose (IAEA CH₆, $\delta^{13}\text{C} = -10.4\text{‰}$), were used for calibration at a precision
11
12 148 of 0.2‰. For nitrogen, international isotope secondary standards of known $\delta^{15}\text{N}$ values,
13
14
15 149 namely (NH₄)₂SO₄ (IAEA N1, $\delta^{15}\text{N} = +0.4\text{‰}$ and IAEA N₂, $\delta^{15}\text{N} = +20.3\text{‰}$) and KNO₃
16
17 150 (IAEA NO₃, $\delta^{15}\text{N} = +4.7\text{‰}$), were used for calibration at a precision of 0.3‰.

18
19
20 151

21 22 152 *Statistical analysis*

23
24 153 Initial statistical screening showed that variances of the $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values between
25
26 154 individual baleen plates were not homogenous according to the Levene test. Moreover, in the
27
28 155 Mediterranean individuals the number of subsamples analyzed was highly dissimilar
29
30 156 between individuals. As a consequence, comparison using the full dataset of samples and
31
32 157 including the “individual” factor as a variable to control for pseudoreplication was not
33
34 158 possible. Therefore, the comparison between whales from the different areas was based on
35
36 159 the mean of all $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values from each specimen, a procedure that was moreover
37
38 160 expected to smooth the seasonal variability likely to exist within the plate. In doing so, the
39
40 161 mean values from each group of whales were normally distributed according to the Lilliefors
41
42 162 test and were homoscedastic according to the Levene test. A t test was used to compare the
43
44 163 two datasets of baleen mean values.

45
46 164 A visual inspection of the raw baleen plate isotope data suggested that Mediterranean and
47
48 165 Atlantic individuals separated into two independent clusters, with the only exception of
49
50 166 individual BP1 from Bentaleb *et al.*^[12] occupying an intermediate position (Figure 2). Linear
51
52 167 discriminant analysis was used to investigate statistical assignment of this controversial
53
54
55
56
57
58
59
60

1
2
3 168 individual to one origin group. The comparison between the isotopic niches of the two
4
5 169 putative subpopulations were carried out by standard ellipses analysis (SEAc) performed
6
7
8 170 using SIBER (Stable Isotope Bayesian Ellipses in R^[26]) as a measure of the mean core
9
10 171 population isotopic niche. The standard ellipse of a set of bivariate data was calculated from
11
12 172 the variance and covariance of the data and contained approximately 40% of the data. SEAc
13
14 173 was considered to be appropriate when analyzing niche widths between groups because it is
15
16
17 174 unbiased with respect to sample size, thus allowing robust comparison among data sets of
18
19 175 different sample size^[26]. Differences in isotopic niche space between two different groups
20
21 176 may indicate differences in the type of prey eaten or differences in the area where they forage.
22
23 177 Convex Hull Area method^[26] (polygon around the most extreme data points on the isotope
24
25 178 bi-plot) was also used to consider the entire variability in the stable isotope values. SEAc and
26
27 179 Convex Hull Area method allowed us to assess the degree of overlap between datasets. In
28
29 180 these analyses, the input data were the isotopic values of all baleen plate subsamples instead
30
31 181 of the mean values from the baleen plates. SEAc and Convex Hull area were performed using
32
33 182 R statistical computing package. The statistical program SPSS 15.0 was used for the other
34
35 183 tests.
36
37
38
39
40
41
42
43

44 185 **Results**

46
47 186 The stable isotope values fluctuated along the longitudinal axis of baleen plates. However,
48
49 187 the pattern of variation was highly variable among individuals, both for the $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$
50
51 188 values. Comparison of mean values between the two datasets revealed that whales from the
52
53 189 Atlantic whales were enriched in both ^{15}N and ^{13}C as compared to those from the
54
55 190 Mediterranean ($t= 4.49$, $df=13$, $p < 0.001$ for $\delta^{13}\text{C}$ and $t= 6.68$, $df=13$, $p < 0.001$ for $\delta^{15}\text{N}$,
56
57
58
59
60

1
2
3 191 $n_{\text{Mediterranean}}=5$, $n_{\text{Atlantic}}=10$ for both stable isotope ratios). Furthermore, the magnitude of the
4
5 192 differences between the two data sets matched the magnitude of the differences between
6
7 193 Atlantic^[24] and Mediterranean^[25] krill (*Meganyctiphanes norvegica*) (Figure 3), thus
8
9 194 confirming that they were not caused by dissimilarities in laboratory procedures.
10
11 195 However, a closer look of the data biplot (Figure 2a, Table 1) revealed a 7.77% overlap
12
13 196 between the convex hull area of the two data sets, but not in the standard ellipses area.
14
15 197 Interestingly, all the Mediterranean samples overlapping with the Atlantic data set came from
16
17 198 a single individual (BP1) that stranded at the core of the north-western Mediterranean
18
19 199 foraging area (Figure 1). The discriminant analysis successfully classified all the samples as
20
21 200 Atlantic or Mediterranean, except those from whale BP1. The resulting discriminant function
22
23 201 was $X = -3.74 + (1.84 \delta^{15}\text{N} + 0.7 \delta^{13}\text{C})$ and the statistics that this function produced for the
24
25 202 eastern North Atlantic population were: centroid (mean): 2.41; standard deviation: 0.99;
26
27 203 ranges: -0.38 to 4.26, and for the Mediterranean population: centroid (mean): -2.92;
28
29 204 standard deviation: 1.00; ranges: -5.03 to -0.66. Accordingly, when the analysis was
30
31 205 repeated with whale BP1 excluded, the Atlantic and Mediterranean whales did not exhibit
32
33 206 any overlap in their stable isotopic values either in the convex hull or in the standard ellipses
34
35 207 area (Figure 2b).
36
37
38
39
40
41
42
43
44
45

46 209 **Discussion**

47
48
49 210 The present study clearly shows that isotopic values, both for $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$, were higher in
50
51 211 the Atlantic individuals than in those from the Mediterranean Sea. In the case of $\delta^{15}\text{N}$ this
52
53 212 could be explained by the two subpopulations feeding at different trophic levels, because
54
55 213 nitrogen stable isotope increases at each trophic level^[19]. This effect should be discarded
56
57
58
59
60

1
2
3 214 because the main prey of fin whales in both areas is almost exclusively *Meganyctiphanes*
4
5 215 *norvegica* (for the Atlantic Ocean^[1,24,27]; for the Mediterranean Sea^[3,23,28]). Therefore, this
6
7
8 216 difference can be more reasonably attributed to different isotopic baselines between the two
9
10 217 areas. Graham et al. (2010)^[22] produced marine carbon and nitrogen isoscapes for the
11
12 218 Atlantic Ocean based on a meta-analysis of published plankton $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values and,
13
14
15 219 according to their maps, both $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ are higher in the northeast Atlantic than in the
16
17 220 Mediterranean Sea, thus matching the differences found here. This scenario is further
18
19 221 supported by the isotopic values in other taxa such as squids^[29] or determined directly in
20
21 222 samples of *M. norvegica* from the two areas (for the Atlantic Ocean^[24] and for the
22
23 223 Mediterranean Sea^[25]) which, after having been corrected for the baleen plate enrichment
24
25 224 factor determined by Borrell et al. (2012)^[22], also matched the results here obtained (Figure
26
27 225 3). Nevertheless, differences between the Atlantic and the Mediterranean are larger and more
28
29 226 consistent for $\delta^{15}\text{N}$ than for $\delta^{13}\text{C}$ values, both for *M. norvegica*^[12,24,25] and whales (this
30
31 227 study).
32
33
34
35
36 228 The only exception to this general rule was one whale analysed by Bentaleb *et al.* (2011)^[12]
37
38 229 that stranded in the Mediterranean (BP1) and whose isotopic values matched better the
39
40 230 Atlantic than the Mediterranean baselines. Because this whale had been sampled about
41
42 231 fifteen years before the other Mediterranean sampled individuals, Bentaleb *et al.* (2011)^[12]
43
44 232 proposed that these higher $\delta^{15}\text{N}$ values might reflect a temporal change in the Mediterranean
45
46 233 $\delta^{15}\text{N}$ baseline. However, in our statistical analyses the discriminant function assigned this
47
48 234 controversial individual with reliability to the Atlantic subpopulation. Moreover, the convex
49
50 235 hull and the standard ellipses analyses performed to define trophic niche similarly matched it
51
52 236 to the Atlantic subpopulation (Figure 2). Further, if this particular individual is examined in
53
54 237 more detail it can be seen that the most recently formed part of the baleen plate had the most
55
56
57
58
59
60

1
2
3 238 depleted value of ^{15}N in the whole plate and, indeed, that value fell within the typical values
4
5 239 found in the Mediterranean individuals. This suggested that the newly-formed layers in the
6
7
8 240 baleen plate were in the process of acquiring the Mediterranean signature, indicating a recent
9
10 241 transit into Mediterranean waters. As a consequence, all evidences indicate that BP1 was
11
12 242 indeed an Atlantic Individual that migrated into the Mediterranean Sea and stranded soon
13
14
15 243 after on the coast of France.

16
17 244 Two individuals (BP8 and BP10) which stranded on the coast of Malaga, this is, in the
18
19
20 245 south-western Mediterranean, matched the isotopic values of Mediterranean whales although
21
22 246 the values of one of them (BP10) were close to the Atlantic data set. It has been proposed that
23
24 247 fin whales visiting this area would indeed be part of the Atlantic subpopulation because the
25
26
27 248 acoustic parameters detected by archival bottom-mounted audio recorders matched those
28
29 249 attributable to the north-eastern North Atlantic subpopulation^[13], so if these two individuals
30
31 250 actually originated from the Atlantic stock they should have had to be foraging in the
32
33
34 251 Mediterranean Sea for at least two years, the approximate period recorded in the baleen
35
36 252 plates analysed.

37
38 253
39
40
41 254 Thus, the information previously available and the results here presented all concur to
42
43 255 confirm the existence of two differentiated subpopulations occurring in the temperate eastern
44
45 256 Atlantic Ocean and the Mediterranean Sea, although the border between them may be not as
46
47
48 257 definite as the acoustic investigations suggested^[13]. Thus, the collective evidence of at least
49
50 258 some individuals with stable isotopic values characteristic of the Atlantic found in the
51
52
53 259 northernmost western Mediterranean Sea, the results from genetic studies pointing to the
54
55 260 existence of some limited exchange^[5] and the movement of one individual tagged with a
56
57
58 261 satellite mark in the Mediterranean that crossed the Straits of Gibraltar and reached the

1
2
3 262 Atlantic coast of central Portugal^[11,12] all confirm the occurrence of recurrent exchange
4
5 263 between the subpopulations inhabiting these two water masses.
6
7

8
9 264 The actual distribution ranges are in both cases difficult to determine. The Mediterranean
10
11 265 subpopulation is known to mainly feed in the Ligurian Sea and in the northern zone of the
12
13 266 Balearic Islands during the summer but afterwards it is thought that it would disperse around
14
15 267 the southern Mediterranean with individuals conducting during the winter sporadic
16
17 268 incursions to de Gulf of Cadiz, the central coast of Portugal or even further north. The ranges
18
19 269 of the temperate eastern North Atlantic subpopulation are more uncertain, particularly
20
21 270 because the very own identity and composition of the subpopulation is unclear. The region
22
23 271 witnessed a severe whaling period during 1921-1927 that resulted during the few years of
24
25 272 exploitation in the catch of over 6,000 individuals^[30]. The Gulf of Cadiz, where observational
26
27 273 records from 19th century open-boat whalers show that the species was originally very
28
29 274 abundant^[31] sustained the bulk of the catch. Afterwards, fin whales almost vanished from the
30
31 275 area; subsequent whaling operations there focused on the sperm whale, with only marginal
32
33 276 catches of fin whales and, even today, after seven decades have passed from the last removals,
34
35 277 the density appears to be extremely low^[14,15]. However, further north, off the coast of Galicia
36
37 278 (NW Spain), whaling was conducted on a clearly more robust subpopulation until 1985,
38
39 279 when a global moratorium on commercial whaling was established by the International
40
41 280 Whaling Commission^[30]. The distinct trajectory of the subpopulations occupying the two
42
43 281 temperate eastern North Atlantic areas has been taken as suggestive of them being
44
45 282 independent stocks, with the one occupying the Gulf of Cadiz having been wiped by the
46
47 283 massive removals made in the 1920s^[32]. The few individuals that are nowadays seen in the
48
49 284 area or crossing the Gibraltar Straits are thought to be either the negligible remains of the
50
51
52
53
54
55
56
57
58
59
60

1
2
3 285 original local subpopulation of the Gulf of Cadiz or stragglers from other neighbouring
4
5 286 subpopulations.
6
7

8
9 287 Results from this study have proved the previously accepted separation between Atlantic and
10
11 288 Mediterranean fin whale subpopulations, but also confirmed that some Atlantic individuals
12
13 289 wander into the Mediterranean Sea and that therefore the subpopulation borders are not as
14
15 290 strict as previously thought^[13]. This is of relevance to the conservation and management of
16
17 291 the species. The discriminant function obtained in this study may assist researchers to use
18
19 292 baleen plate isotopic data to assign the origin of fin whales of uncertain provenance. Further
20
21 293 research is needed to more precisely determine the degree of connectivity between the
22
23 294 subpopulations and the actual location of their boundaries. Stable isotope studies conducted
24
25 295 in combination with genetics, particularly on fin whales sampled at the Gibraltar Straits and
26
27 296 neighbouring areas from where potential stragglers may stem from, may assist in establishing
28
29 297 demographic structure, as has been the case with other balaenopterid species^[33].
