19 **ABSTRACT**

20 The urgency to move from critical raw materials to highly available and renewable feedstock is

21 currently driving the scientific and technical development. Within this context, the abundance of

22 natural resources like chitosan paves the way to synthesize biomass-derived nitrogen-doped

23 carbons. This work describes the synthesis of chitosan-derived N-doped mesoporous carbon in the

24 absence (MC-C) and presence (N-MC-C) of 1,10-phenanthroline, which acted as both porogen

25 agent and as second nitrogen source. The as-prepared MC-C and N-MC-C were thoroughly

26 characterized and further employed as catalytic materials in gas-diffusion electrodes (GDEs),

27 aiming to develop a sustainable alternative to conventional GDEs for H_2O_2 electrogeneration and

28 the photoelectro-Fenton (PEF) treatment of a drug pollutant. N-MC-C presented a higher content

29 of key surface N-functionalities like pyrrole group, as well as an increased graphitization degree

30 and surface area (63 vs. 6 m^2/g), being comparable to commercial carbon black. These properties

31 entailed a superior activity of N-MC-C for the oxygen reduction reaction, as confirmed from its

32 voltammetric behavior at a rotating ring-disk electrode. The GDE prepared with N-MC-C catalyst

33 showed greater H_2O_2 accumulation, attaining values close to those obtained with a commercial

34 GDE. N-MC-C- and MC-C-derived GDEs were employed to treat drug solutions at pH 3.0 by PEF

35 process, which outperformed electro-oxidation (EO). The fastest drug removal was achieved using

36 N-MC-C, needing only 16 min at 30 mA/cm^2 instead of 20 min required with MC-C. The

37 replacement of the dimensionally stable anode by a boron-doped diamond (BDD) accelerated the

38 degradation process, reaching an almost complete mineralization in 360 min. The main

39 degradation products were identified, revealing the formation of six different aromatic

40 intermediates, alongside five aliphatic compounds that comprised three nitrogenated structures.

41 The initial N was preferentially converted into ammonium.

43 carbon; Organic pollutant; Oxygen reduction reaction

INTRODUCTION

Lately, selected single atoms[1] as well as polyatomic Co-based compounds[2-4] have been successfully tested to electrocatalyze the two-electron oxygen reduction reaction (ORR, reaction (1)) to hydrogen peroxide.

$$O_{2(g)} + 2H^+ + 2e^- \leftrightarrows H_2O_2 \qquad E^0 = 0.695 \text{ V} \qquad (1)^{[5]}$$
Nonetheless, the development of metal-free electrocatalysts derived from cheap and environmentally friendly biomasses for ORR promotion has become a relevant topic,[6] especially within the context of circular economy. Carbon-based materials combine low cost and environmental impact with high stability, features that make them suitable candidates for H_2O_2 generation in actual devices.[7-9] Likewise, porous carbonaceous materials with N-[10] or S-containing[11] surface functionalities, or both,[12-14] have shown promising electroactivity and selectivity for reaction (1).

To obtain nitrogenated carbon catalysts with high ORR performance and selectivity, three aspects need to be taken into account: (a) the type of N species, which determine the selectivity and the activity of the reaction sites;[10] (b) the architecture, in particular the surface area and porous structure; and (c) the degree of graphitization, which determines the conductivity and stability of the material. Both, experimental studies and theoretical calculations, confirmed that the ORR activity of nitrogen-doped carbon materials originates from the charge delocalization of the carbon atoms due to nitrogen incorporation, which facilitates oxygen adsorption and reduction. The activity was reported to be highly dependent on the doping level and types of nitrogen atoms.[10,12] Nitrogen functional groups can be pinned onto the carbon surface following three different strategies: (i) post-functionalization of undoped carbon, by means of ion implantation,[15] ball milling[16] or grafting;[17] (ii) simultaneous carbonization and doping, feasible via activation procedures like ammonia pyrolysis;[18] and (iii) use of a suitable carbon-nitrogen precursor to carry out the pyrolysis process.[12,13,19-22] Such precursors are N-containing organic molecules or

polymers, such as 1,10-phenthroline and polyaniline, but a plethora of examples starting from biomasses can be found in the literature.[5,23] Examples of transformation of N-containing biomass into N-doped carbons for ORR include the use of cellulose, algae, flowers, fruits or bamboo.[24-32]

Considering any new carbonaceous electrocatalyst of interest, a simple cathode for massive H_2O_2 production could be prepared by coating a three-dimensional substrate, such as a carbon felt.[20,33] This type of substrate enhances the hydrodynamics and mass transport of oxygen,[34] which must be continuously dissolved in the aqueous solution by conventional[33,35,36] or advanced[37] means. Alternatively, the incorporation of an air chamber to the reactor enables a much greater oxygen concentration, thereby enhancing the H_2O_2 production.[5] In such setup, either oxygen or air would be fed to a hydrophobized microporous[38] or macroporous[39] substrate coated with the electrocatalyst, being the ensemble called gas-diffusion electrode (GDE).

Hitherto, GDEs for H_2O_2 electrogeneration have been mostly manufactured using carbon black produced via hydrocarbon pyrolysis,[2,40-44] although other carbon materials like carbon nanotubes[3,4,45] or graphene[46] have also been employed. Fewer insight has been provided on mesoporous carbon,[12,13] whose ordered structure can minimize the residence of the generated H_2O_2 in the reaction zone.[47] Currently, the H_2O_2 production with GDEs finds its main application in water treatment, especially for the degradation of hardly biodegradable organic pollutants through advanced oxidation processes like electro-Fenton (EF) ones.[48-50] In EF, the very reactive $^{\bullet}OH$ generated from Fenton's reaction (2) allows overcoming the limitations of conventional technologies.[51]

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + {}^{\bullet}OH + OH^- \tag{2}$$

An upgraded version of EF involves the concomitant exposure of the treated solution to UVA light, originating the photoelectro-Fenton (PEF) process,[52] whose main contribution is the photo-induced Fe^{2+} regeneration as follows, favoring its immediate consumption via reaction (2):[3,4,53,54]

$$[Fe(OH)]^{2+} + h\nu \rightarrow Fe^{2+} + {}^{\bullet}OH \tag{3}$$

4
94   N-doping of carbons to manufacture GDEs suitable for EF or PEF has been scarcely studied.

95   The presence of N increased the electroactivity of a cathode composed of carbon nanotubes coated

96   with graphene, ending in a faster degradation of dimethyl phthalate by EF.[55] N-doped carbon

97   prepared from 1H-1,2,4-triazole-3,5-diamine showed the highest ORR rate among other materials,

98   yielding a faster EF degradation of sulfathiazole.[56] The number of studies is even lower in the case

99   of biomass-derived carbons for H_2O_2 production with GDEs. As far as we know, Liao et al.[57] have

100   reported the only article on the topic, which discusses the performance of a GDE made of N-doped

101   mesoporous carbon coming from bean dregs. They simply used the cathode to generate H_2O_2 for

102   formaldehyde degradation, which means that the investigation of biomass-derived GDEs in EF

103   and PEF is a quite unexplored field.

104   Aiming to conceive more eco-friendly EF and PEF approaches for water treatment, herein

105   chitosan has been chosen as a suitable N-containing biopolymeric gel precursor for preparing

106   mesoporous carbon material (MC-C) in virtue of its biocompatibility, biodegradability and high N

107   content (7.1%). It is worth noticing that raw chitosan has been included in some EF systems so

108   far, mainly in the form of composite with iron species to promote heterogeneous Fenton's

109   reaction,[58] although as far as we know it was never incorporated in the form of carbon powder.

110   Chitin and its derivative chitosan are among the most abundant organic compounds in nature,

111   easily obtained from crustacean shells and further purified,[59] which makes them adequate for a

112   wide range of applications.[60] The physicochemical characterization of the synthesized catalysts

113   was performed by different techniques. Their ability to electrogenerate H_2O_2 was assessed by

114   means of cyclic voltammetry (CV) and linear sweep voltammetry (LSV), as well as via bulk

115   electrolyses. In addition, the comparative degradation ability of the two catalysts was investigated

116   by treating 150 mL of acebutolol solutions at acidic pH. The selection of the contaminant is

117   justified by the growing complexity of global water pollution associated to pharmaceuticals due

118   to both, diversity of target molecules and large volume of effluents. Standard water treatments are

119 frequently unable to ensure total detoxification, which urges more advanced technologies.[61] The

120 hypotensive and antiarrhythmic acebutolol is excreted mostly in its unmetabolized form and hence,

121 it is accumulated alongside its intermediates in surface water,[62] as well as in sewage treatment

122 plant effluents, evidencing a low biodegradability.[63] This represents a serious threat, since

123 acebutolol is toxic for aquatic organisms[64] and causes lupus-like syndrome.[65] Herein, the PEF

124 process was assessed for the first time for acebutolol remediation.

125 **MATERIALS AND METHODS**

126 **Chemicals.** Chitosan (> 98%, Aldrich for Life Science) and 1,10-phenanthroline (> 99.5%,

127 TCI) were used as received. Other reagents employed for the synthesis of catalysts were: pure

128 ethanol (> 99.8%, Fluka), Nafion® (5 wt % in a mixture of lower aliphatic alcohols and water,

129 Sigma Aldrich), acetic acid (> 99.8%, Sigma Aldrich), acetone (> 99.5%, Sigma Aldrich), H_2SO_4

130 (95%, Fluka) and NaOH (> 99%, VWR). Each catalyst was mixed with ethanol (96%, Panreac)

131 and polytetrafluoroethylene (PTFE, 60 wt % solution, Sigma-Aldrich), following the procedure

132 described below, to manufacture a GDE. The specific reagents required for the bulk electrolytic

133 trials   were: acebutolol   (N-[3-acetyl-4-[2-hydroxy-3-(propan-2-

134 ylamino)propoxy]phenyl]butanamide) in the form of a hydrochloride salt ($C_{18}H_{28}N_2O_4$·HCl, CAS

135 number 34381-68-5, Sigma-Aldrich), Na_2SO_4 (anhydrous, Merck) and $FeSO_4$·$7H_2O$ (Panreac).

136 Acetonitrile and KH_2PO_4 used to quantify acebutolol, as well as CH_2Cl_2 employed in gas

137 chromatography-mass spectrometry (GC/MS), were of high performance liquid chromatography

138 (HPLC) grade from Panreac. Other chemicals needed for the analytical procedures described

139 below included: Ti(IV) oxysulfate (technical grade, Sigma-Aldrich) to determine the H_2O_2

140 concentration; phenol (99.5%, Sigma-Aldrich), sodium nitroprusside dehydrate (Merck) and

141 ethylenediaminetetraacetic acid disodium salt dehydrate (99%, Alfa Aesar) to quantify ammonium

142   ion. Ultrapure water for synthesis, manufacture, electrolysis and analysis was obtained from a

143   Millipore Milli-Q system (Merck).

144   **Synthesis of the catalysts.** The synthesis of carbon electrocatalysts from chitosan was

145   accomplished by modifying a procedure reported in the literature.[66,67] Chitosan was employed as

146   source of both carbon and nitrogen since it is composed of repeating units of randomly distributed

147   β-(1→4)-linked D-glucosamine and N-acetyl-D-glucosamine. The synthesis consisted in the

148   formation of a chitosan hydrogel followed by the removal of the solvent by freeze drying and the

149   pyrolysis of the resulting material. The hydrogel synthesis involved the dispersion of the chitosan

150   powder (1.8 g) in an acetic acid solution (100 mL, 2 vol %), and the resulting mixture was

151   vigorously stirred to ensure the complete solubilization. In fact, at acidic pH, the amine groups in

152   the N-acetyl-β-(D)-glucosamine moiety are protonated to ammonium (pK_a (-NH_3^+) = 6.3),[68] which

153   disrupts the hydrogen bonds between the polymer chains and leads to the collapse of the chitosan

154   crystalline structure and to the solubilization of the polymer in water, finally obtaining a

155   transparent, homogeneous and viscous solution (Figure 1a). The hydrogel formation then occurred

156   by slowly pouring a 1 M NaOH solution to the chitosan viscous solution. Since the diffusion of

157   OH^- ions is slow, the gelation was not instantaneous, but the gelation front advanced at the

158   hydrogel/NaOH solution interphase as the hydroxide ions diffused through the chitosan solution

159   (Figure 1b). The alkaline pH favored the deprotonation of the -NH_3^+ groups, promoting the

160   interaction between polymeric chains by hydrogen interactions along with the incorporation of the

161   solution between the chitosan chains, yielding the hydrogel. Once the gelation was concluded, the

162   hydrogel was repetitively rinsed with water until a neutral pH was reached (Figure 1c).

163   Subsequently, the gel was cut into small pieces with a chisel and freeze-dried to remove all water.

164   The dried gel (Figure 1d) was then thermally treated in a two-step pyrolysis procedure.[28] The gel

165   was heated in a Carbolite tubular furnace with a 75 sccm (standard cm^3/min) N_2 flux at 100 °C for

166   1 h, after which the temperature was raised up to 400 °C at a rate of 5 °C/min and kept at that

temperature for 2 h. The resulting powder (0.72 g) (Figure 1e), was ground by vibro-milling (Retsch MM 400, four steps of 4 min/10–25 Hz) (Figure 1f) and eventually re-pyrolyzed at 900 °C for 2 h under nitrogen atmosphere (Figure 1g). The obtained carbon powder (MC-C, 0.52 g) was washed with water and ethanol, dried at 80 °C overnight and ground by vibro-milling.

Alternatively, phenanthroline was used as secondary source of nitrogen and was added (0.3 g) to the initial chitosan/acetic acid solution, and the mixture was stirred and allowed to gel after the addition of NaOH solution. This procedure allowed to finely disperse phenanthroline all over the hydrogel, avoiding the preferential functionalization of the resulting carbon catalyst and formation of a heterogeneous material. It is worth noting that part of the added phenanthroline was washed away during the neutralization procedure with deionized water, as was confirmed by the presence of the typical UV-Vis adsorption pattern of phenanthroline in the washing water (Figure S1). Conversely, phenanthroline was detected only in traces in the water extracted during the freeze-drying procedure (Figure S1). The resulting dried gel was subjected to a double pyrolysis at 400 and 900 °C, followed by ball milling as in the previous case. The catalyst obtained starting from 1,10-phenthroline and chitosan will be denoted from now on as N-MC-C.

Physicochemical characterization of catalyst powders. Brunauer-Emmett-Teller (BET) analysis, isotherm and pore distribution were performed via nitrogen adsorption-desorption at 77 K using the Micromeritics ASAP2020. The surface area was determined from the desorption curve in a multipoint BET analysis, whereas the pore distribution was analyzed with a slit/cylindric pore NLDFT equilibrium model. Elemental analysis (EA) was carried out using a Thermo Scientific Flash 2000 device. Transmission electron microscopy (TEM) images were obtained by using a FEI Tecnai G2 transmission electron microscope operating at 100 kV. X-ray photoemission spectroscopy (XPS) measurements were performed in an UHV chamber (base pressure $< 5 \times 10^{-10}$ mbar), equipped with a double anode X-ray source (omicron DAR-400), a hemispherical electron analyzer (omicron EIS-125) at room temperature, using non-monochromatized Mg-Kα radiation

192 ($h\nu = 1253.6\,eV$) and a pass energy of 50 and 20 eV for the survey and the single spectral windows,

193 respectively. To perform the XPS measurements, 2.5 mg of carbon powders were dispersed in 1

194 mL of ethanol and then sonicated for 10 min in order to obtain good dispersions; the solutions

195 were then drop-casted onto polycrystalline copper (with a diameter of 6 mm). Raman scattering

196 experiments were conducted with a DXR Raman microscope system (Thermo Fisher Scientific),

197 with a 532 nm laser as the photoexcitation source. The size of the laser spot at the sample was

198 about 25 μm and the power at the sample was 0.1, 0.5 or 1.0 mW.

199 **Electrochemical characterization of catalyst powders.** CV and LSV analysis at a rotating

200 ring disk electrode (RRDE, Metrohm; 5 mm diameter glassy carbon (GC) disk + Pt ring, with a

201 collection efficiency of 25% were performed in both Ar-purged and O_2-saturated 0.0005 M H_2SO_4

202 + 0.050 M Na_2SO_4 solutions by using an Autolab Model 101 N potentiostat/galvanostat. A three-

203 electrode configuration was used, consisting in a GC disk (geometric area of 0.196 cm^2) as working

204 electrode, a graphite rod as counter electrode, and a reversible hydrogen electrode (RHE) as

205 reference electrode. The latter was freshly prepared before each experiment and consisted in a Pt

206 wire mesh sealed to the closed end of a capillary glass tube and refilled with the electrolyte solution

207 from the other open end. H_2 was directly electrogenerated at the Pt wire mesh so that half of the

208 Pt mesh was exposed to the H_2 bubble confined between the electrolyte solution and the closed

209 end of the capillary.[69]

210 The MC-C and N-MC-C catalysts were characterized as thin films prepared by drop-casting

211 an ink (20 μL) of the corresponding carbon powder on a GC disk. Before the drop casting, the GC

212 was polished to a mirror finish with Struers silicon carbide papers of decreasing grain size (grit:

213 500, 1000, 2400, 4000) followed by diamond paste (3-, 1-, 0.25-mm particle size) and repeatedly

214 washed and sonicated (10 min each time) in ethanol for removing all contaminants.

215 All the electrochemical assays were carried out with an optimized loading of 0.6 mg/cm^2. The

216 electrolyte was purged with Ar before each measurement, whereas for the ORR test, high-purity

217 O_2 gas was bubbled through the electrolyte for at least 1 h to ensure O_2 saturation. The number of

218 electrons transferred during ORR was determined by the RRDE technique. Before data acquisition,

219 the electrocatalysts were first activated by cycling the electrode in the solvent potential window at

220 200 mV/s until obtaining a stable cyclic voltammogram.

221 **Fabrication of the gas-diffusion cathodes.** A GDE was prepared from each type of

222 synthesized powder using the spraying method.[3,4] An appropriate amount (0.1 g) of MC-C or N-

223 MC-C powder was ultrasonically dispersed with PTFE and ethanol for 45 min to obtain an ink (∼

224 20 mL). Carbon cloth (∼8 cm^2 geometric area, BASF B1ASWP), degreased in ethanol and then

225 dried at 60 °C for 3 min, was used as substrate to spray the ink. An air-brush gun fed with N_2 gas

226 was employed to apply several layers, until the ink was finished. After each layer, the material was

227 dried at 60 ºC for 3 min and then weighted. The sample was pressed at 2 ton for 45 s, annealed at

228 400 °C for 60 min under nitrogen atmosphere and finally cooled down at ambient conditions. The

229 overall weight increment in each GDE was ∼80 mg (i.e., MC-PTFE loading of 9.7 mg/cm^2). In

230 order to use any new GDE, it was first activated conducting a galvanostatic polarization in 0.050 M

231 Na_2SO_4 at pH 3.0 for 60 min.

232 The morphological characteristics of the GDEs before and after use were assessed by

233 scanning electron microscopy (SEM) using a JEOL JSM-7100F field-emission microscope

234 equipped with an energy-dispersive X-ray spectroscopy analyzer. All images were obtained at a

235 voltage of 20.0 kV.

236 **Bulk electrolyses and analyses.** Electrolytic trials were conducted for several hours in the

237 absence and presence of pollutant to evaluate the H_2O_2 electrogeneration ability of GDEs and the

238 degradation performance of different processes, respectively. In all these trials, a given GDE (3

239 cm^2) prepared as described above was placed in a tubular polypropylene housing that received

240 compressed air pumped at 36 L/h, and such cathode was connected to the anode (3 cm^2). The latter

241 consisted in a RuO_2-based plate (i.e., dimensionally stable electrode, DSA) from NMT Electrodes

242 in most of the trials, although boron-doped diamond (BDD) from NeoCoat was also employed in

243 some cases. The distance between the anode and cathode was 1.0 cm. The assays were performed

244 in an undivided glass cell, which was placed onto a magnetic stirrer operated at 700 rpm and

245 contained 150 mL of solution at pH 3.0 and thermostated at 25 ℃. All treatments were made in

246 the presence of 0.050 M Na_2SO_4 as background electrolyte and, when required, acebutolol was

247 added at a concentration of 0.046 mM, i.e., 10 mg/L total organic carbon (TOC). In EF and PEF,

248 Fe^{2+} catalyst was added before starting the electrolysis at a concentration of 0.50 mM. In the photo-

249 assisted treatment, the solution was illuminated with UVA photons from a 6 W Philips tubular

250 lamp (λ_{max} = 360 nm, irradiance of 5 W/m^2) placed above the reactor near the liquid surface.

251 Constant current was always supplied by an Amel 2051 potentiostat-galvanostat, whereas the cell

252 voltage (E_{cell}) was continuously displayed by a Demestres 605 multimeter.

253   When required, the pH of solutions was measured with a Crison GLP 22 pH-meter.

254 Colorimetric analysis of the complex formed between Ti(IV) and H_2O_2 was made using an Unicam

255 UV/Vis spectrophotometer set at λ_{max} = 408 nm, with solutions thermostated at 25 °C. The content

256 of ammonium ion was measured with the same equipment, according to the indophenol blue

257 method, at λ_{max} = 630 nm.[3] TOC was determined using the non-purgeable organic carbon (NPOC)

258 mode of a Shimadzu TOC-VCNS analyzer. Acebutolol concentration was determined by reversed-

259 phase HPLC, with a Waters 600 apparatus equipped with a C18 column at 35 ℃ connected to a

260 photodiode array detector. A well-resolved peak appeared at retention time of 4.6 min (λ = 235

261 nm). The mobile phase was a mixture of acetonitrile (40 vol %) and water (10 mM KH_2PO_4 at pH

262 3.0, 60 vol %), circulating at 1.0 mL/min. Trials were made in duplicate and injections in triplicate

263 to correctly assess the drug disappearance. Hence, average values are shown in the figures

264 alongside the error bars (95% confidence level). The final carboxylic acids were quantified as

265 previously reported, by injecting the samples in the same chromatograph but equipped with an

266   Aminex column.[39] Before each analysis, the samples were conditioned by filtration with PTFE

267   filters (13 mm × 0.45 µm, Whatman).

268   Current efficiency (CE) values during the H_2O_2 electrogeneration were calculated from the

269   applied charge, according to the Eq. (4):[5]

270    $$CE\ (in\ \%) = \frac{2F[H_2O_2]V}{1000M(H_2O_2)Q}100 \qquad (4)$$

271   where 2 is the stoichiometric number of electrons transferred for ORR to form H_2O_2, F is the

272   Faraday's constant (96,487 C/mol), $[H_2O_2]$ is the concentration of accumulated H_2O_2 (mg/L), V is

273   the volume of the treated solution (L), 1000 is a conversion factor, $M(H_2O_2)$ is the molecular

274   weight of H_2O_2 (34 g/mol), and Q is the charge consumed during the electrolysis.

275   The mineralization current efficiency (MCE) for each trial at a given electrolysis time t (in h)

276   and applied current I (in A) was calculated as follows:[70]

277    $$MCE\ (in\ \%) = \frac{nFV(\Delta TOC)_{exp}}{4.32x10^7mIt}100 \qquad (5)$$

278   where n accounts for the number of electrons consumed for the overall mineralization of the drug,

279    $\Delta(TOC)_{exp}$ is the observed TOC decay (in mg/L), 4.32×10^7 is a conversion factor (= 3600 s/h ×

280   12000 mg C / mol) and m is the number of carbon atoms of acebutolol (18 atoms).

281   The specific energy consumption per unit TOC mass (EC_{TOC}) was obtained as follows:[70]

282    $$EC_{TOC}\ (in\ kWh\ /\ g\ TOC) = \frac{E_{cell}It}{V(\Delta TOC)_{exp}} \qquad (6)$$

283   where E_{cell} is the average cell voltage (in V).

284   The primary reaction products were identified by GC/MS. For this, samples collected after

285   selected electrolyses were prepared by liquid-liquid extraction with CH_2Cl_2 as organic solvent.[36]

286   The GC/MS analysis was made in electron impact mode at 70 eV with an Agilent Technologies

287   system: a 6890N gas chromatograph with a 7683B series injector was connected to a 5975 mass

288   spectrometer. Non-polar Teknokroma Sapiens-X5.ms and polar HP-INNOWax columns, both

289   with dimensions of 0.25 µm, 30 m x 0.25 mm (i.d.), were used. When using the former, the

290   conditions were: temperature ramp starting at 36 ºC for 1 min and increasing up to 320 ºC at 5

291   ºC/min (hold time 10 min); the temperature of the inlet, source and transfer line was 250, 230 and

292   300 ºC, respectively, and the analyses were made by splitless (0.7 min) injection, with run time of

293   67.80 min. When the latter was employed, the conditions were analogous but the final temperature

294   was 250 ºC, with 250 ºC as the temperature of the transfer line and 93.80 min as run time.

295   **RESULTS AND DISCUSSION**

296   **Characterization of synthesized catalysts.** Nitrogen-doped carbon is a term commonly

297   accepted by the scientific community to classify carbon powder containing nitrogen functional

298   groups. In the present paper, the pyrolysis of the pure dried chitosan hydrogel as well as of the

299   dried hydrogel embedding 1,10-phenanthroline yielded two samples, denoted as MC-C and N-

300   MC-C, respectively. The three-dimensionality of chitosan hydrogels allows the fine dispersion of

301   additives inside the gel structure, which can improve the functionalization of the carbon structure

302   and enhance the textural properties resulting from thermal treatment. A double step pyrolysis, at

303   400 and 900 °C, was employed for decreasing the burn off of the material, and the resulting black

304   powder was characterized after ball milling.

305   Figure 2 highlights the TEM images of the two types of carbon powder at different

306   magnifications. The structure of the MC-C sample is characterized by the overlay of compact

307   carbon lamellae (Figure 2a-c), in which any pore structure is clearly visible. The morphological

308   features of MC-C are in part superimposable with those of N-MC-C (Figure 2d-f). However, the

309   lamellar structures are in this latter case characterized by a less packed and compact structure,

310   presenting more jagged edges.

311   Table 1 reports the elemental analyses of the synthetized carbons. MC-C, prepared by

312   employing the sole chitosan as both carbon and nitrogen precursor, shows a nitrogen fixation of

313   almost 7%, as evidenced by the CHN analysis. Then, it must be clear that the notation MC-C

13

314   simply means that an additional N-rich precursor was not employed during the synthesis. Also the

315   oxygen content, which in first approximation can be calculated as the residual mass percentage, is

316   sensitively high (~16%). Therefore, it is reasonable to infer that the MC-C carbon was rich in

317   nitrogen and oxygen functional groups, which are extremely important as active sites to

318   electrocatalyze some reactions as well as for increasing the wettability of the electrode material

319   during the electrocatalytic tests. A close comparison with the values obtained for the N-MC-C

320   sample (Table 1) allows noticing that, when 1,10-phenthroline was used as a secondary nitrogen

321   source during the chitosan hydrogel preparation, the resulting carbon had a higher carbon and

322   hydrogen content but a lower nitrogen ($< 5\%$) and oxygen ($< 15\%$) percentage as compared to

323   MC-C. We can presume that the pyrolysis of 1,10-phenanthroline generates small gaseous

324   molecules such as NO, NO_2 and CO, which may act as oxidizing agents able to react with the

325   amorphous part of the carbon structure, i.e., the sp^3 carbon atoms bonded to nitrogen and oxygen

326   functional groups, while the more graphitic sp^2 are preserved, being less prone to react with in situ

327   generated reactive species.

328   The nitrogen adsorption/desorption isotherms at 77 K for MC-C belong to the type II, which

329   is characteristic for non-porous or macroporous materials having a relatively small external surface

330   (Figure 3a). However, the TEM pictures do not show the presence of macropores (Figure 2a-c),

331   which would correspond to pores with diameters wider than 50 nm, being reasonable to conclude

332   that MC-C can be classified as a non-porous carbon material. The sample showed a non-reversible

333   desorption behavior with an open hysteresis loop classified as type-H4, which is often attributed

334   to narrow slit-like pores.[71] The very low value of mesopore volume (Table 1) can be associated to

335   the collapse of the mesopore structure during the gas desorption or to the entrapment of N_2 gas in

336   narrow pores formed between two carbon foil, which could also explain the open hysteresis.[72]

337   However, the experiment was repeated a second time, showing the very same behaviour and hence,

338   the first hypothesis of a carbon structure collapse can be disregarded, being the irreversible

14

339 confinement of N_2 molecules between carbon foils the most probable explanation. The

340 extrapolated BET surface area was as small as $A_{BET} = 6$ m^2/g. Figure 3a also reports the type II

341 nitrogen adsorption/desorption isotherm for N-MC-C. Similarly, in this case the open hysteresis

342 loop can be classified as type-H4, and an analogous conclusion can be drawn regarding the open

343 hysteresis. It is worth noting that the presence of 1,10-phenantroline in the dried hydrogel affected

344 very positively the BET surface area, which was enhanced up to 63 m^2/g in N-MC-C. In this case,

345 the more pronounced uptake at low p/p^o can be associated with an enhanced adsorbent-adsorbate

346 interaction in narrow micropores.[72] The large area was directly related to the increased porosity

347 (Table 1), which was mainly due to micropores ($d < 2$ nm, $V_\mu = 0.021$ cm^3/g), along with a

348 mesopore fraction (2 nm $< d <$ 50 nm, $V_{meso} = 0.017$ cm^3/g). The formation of micropores and

349 mesopores or the simple opening of clogged pores can be associated to the reaction of NO, NO_2

350 and CO gaseous species, generated during the pyrolysis of 1,10-phenanthroline with the carbon

351 structure while CO_2 is released.[73,74] The pronounced uptake at high p/p^o is indicative of the

352 presence of macropores ($d > 50$ nm), which cannot be in any case evaluated in terms of pore

353 volume and area by the adopted model. However, the presence of a more open and accessible

354 structure finds a confirmation in the TEM images described above. Note that the higher porosity

355 of N-MC-C as compared to MC-C is also evident from the greater total volume (V_{TOT}) summarized

356 in Table 1 (0.065 vs 0.013 cm^3/g, respectively). Therefore, while MC-C is a non-porous carbon

357 material, N-MC-C can be classified as a carbon material with low porosity and textural properties

358 similar to those of commercial carbon black ($A_{BET} = 67$ m^2/g, $V_\mu = 0.015$ cm^3/g, $V_{meso} = 0.137$

359 cm^3/g).

360 The MC-C and N-MC-C samples were characterized by Raman spectroscopy, which allows

361 elucidating the possible differences in the order and aggregation degree of sites with sp^2

362 hybridization and, more in general, informs about the amorphous and graphitized degree of a

363 carbon material (Figure 3b).[75] Soft and hard carbon materials typically show two main bands: the

364   D1 (disorder) at ~1350 cm^{-1} and the G (graphitic) at ~1595 cm^{-1}, as corroborated also for the MC-

365   C and N-MC-C samples. The 2D peak at ~2680 cm^{-1}, ascribed to an out-of-plane vibration mode

366   and generally present in graphite, single layer graphene or highly graphitized carbon is missing,

367   but a broad band between 2400 and 3000 cm^{-1} is present in both samples. The spectra

368   deconvolution revealed the existence of four bands after baseline subtraction and normalization to

369   the maximum of the G band. The two further bands D4 and D3 account for polyenes or ionic

370   impurities and amorphous carbon, respectively. The resulting I_{D1}/I_G band intensity ratio was close

371   to one for both samples (Figure S2). According to the Tuinstra-Koenig model, the following

372   relationship is satisfied:[76]

373
$$\frac{I(D1)}{I(G)} = \frac{C(\lambda)}{L_a} \tag{7}$$

374   where $C(\lambda) = -12.6 + (0.033\lambda) \approx 50$ Å, ($\lambda = 532$ nm) and thus, the band intensity ratio can be used

375   to determine the size of the graphite nanocrystallites, which was 4.7 and 5.0 nm for MC-C and N-

376   MC-C, respectively. A close comparison of the two spectra allows observing two main differences:

377   (i) the D1 intensity was higher in the MC-C spectrum than in the N-MC-C one; and (ii) the valley

378   (minimum intensity point) between the D1 and G band was higher in MC-C than in N-MC-C. Both

379   characteristics lead to conclude that N-MC-C was more graphitized than MC-C. This can be further

380   confirmed by considering the D3 band area, responsible for the amorphous carbon, which resulted

381   lower in N-MC-C (37.6 normalized counts) with respect to MC-C (41.6 normalized counts).

382   The XPS analyses confirmed the presence of nitrogen, oxygen and carbon in both samples

383   (Table 1 and Figure S3). The higher percentage of oxygen in MC-C with respect to N-MN-C

384   confirmed that the introduction of 1,10-phenanthroline contributed to a greater graphitization.

385   Figures 3c and 3d and Table S1 show the C 1s XPS data of the analyzed samples. The main carbon

386   component at binding energy (B.E.) = 284.4 eV was attributed to C-sp^2.[12,15,77] At higher B.E.

387   (285.4 eV) the peak corresponded to the sp^3 C-C bond. The higher sp^2/sp^3 ratio in N-MC-C as

388   compared to MC-C sample is in agreement with the observations from Raman analysis (Table S1).
389 There was also a substantial amount of carbon bound to nitrogen or/and to oxygen (peak at 286.4

390 eV). Peaks at B.E. higher than 286.4 eV were due to carbon species bound to oxygen (C=O, O-

391 C=O, O-C(O)-O) or to both oxygen and nitrogen (C-N=O, N-C=O). Peak at 291.1 eV was due to

392 shakeup satellite (π-π^*).

393   The N 1s spectra and their deconvolution in single peaks are reported in Figure 3e and 3f. The

394 elemental analysis determined from XPS data indicates a weight percentage of surface nitrogen of

395 2.6% and 3.4% for MC-C and N-MC-C, respectively, in contrast to the above mentioned CHN

396 analysis, which is a bulk sensitive technique that detected a greater nitrogen content in the MC-C

397 sample (Table 1). Therefore, it is reasonable to assert that in the MC-C catalyst the nitrogenated

398 functional groups are mostly confined in the bulk of the carbon material, whereas the pyrolysis of

399 chitosan hydrogel carried out in the presence of 1,10-phenanthroline leads to a higher surface

400 nitrogen content, thereby providing a higher number of available active sites. This is a key finding

401 that justifies the presence of the additional N-containing precursor during the synthesis, since the

402 resulting surface N-functionalities are expected to induce a higher H_2O_2 electrogeneration. The

403 speciation of the singular N 1s components evidences the presence of pyridinic, imine, amine and

404 pyrrolic nitrogen (Table 1). Graphitic and nitrogen oxide components were also present in lower

405 percentage.[12,28] It is interesting to observe that the pyrrolic component significantly increases in

406 N-MC-C. Both, pyridinic and pyrrolic nitrogen are beneficial groups since they increase the carbon

407 activity versus ORR and, more in particular, it is reported that pyrrolic nitrogen favors the bi-

408 electronic reduction of oxygen to hydrogen peroxide.[17,27,30]

409 **Electroactivity of chitosan-derived catalysts.** MC-C and N-MC-C were both

410 electrochemically characterized in 0.0005 M H_2SO_4 + 0.050 M Na_2SO_4 as background electrolyte,

411 aiming to determine their activity regarding the oxygen reduction and their corresponding

412 selectivity towards the H_2O_2 generation. Figure 4a and 4b compare the electrochemical behaviour

413 in Ar-purged and O_2-saturated electrolyte using MC-C and N-MC-C electrocatalyst, respectively.

414   No redox signal appeared in the purged medium, whereas both materials showed electroactivity

415   versus ORR, as deduced from the well-defined reduction peak that was visible in the presence of

416   dissolved O_2. The O_2 reduction peak potential using the N-MC-C (0.525 V vs RHE) was 190 mV

417   more positive than that obtained with the MC-C (0.335 V vs RHE). The smaller overpotential

418   required using the N-MC-C informs about its higher activity with respect to MC-C, which can be

419   attributed to the aforementioned greater content of nitrogen groups on the N-MC-C surface (Table

420   1).

421   The ORR may proceed through two pathways: one is a direct four-electron route, which

422   consists in the direct O_2 reduction to water without involvement of H_2O_2 (reaction (8)); the other

423   is a two-step two-electron route in which H_2O_2 is first formed as intermediate via the 2-electron

424   reaction (1), and then it can potentially undergo further reduction via reaction (9).

425   $$O_{2(g)} + 4H^+ + 4e^- \leftrightarrows 2H_2O \qquad E^0 = 1.229 \text{ V} \qquad (8)^5$$

426   $$H_2O_2 + 2H^+ + 2e^- \leftrightarrows 2H_2O \qquad E^0 = 1.763 \text{ V} \qquad (9)^5$$

427   The selectivity towards the formation of H_2O_2 was evaluated by LSV using an RRDE in O_2-

428   saturated electrolyte at a scan rate of 10 mV/s and rotation speed (ω) of 1600 rpm. During RRDE

429   experiments, the potential of the disk electrode was swept to cathodic values, so that the

430   appearance of a current (I_D) in the linear voltammogram using MC-C and N-MC-C confirmed the

431   reduction of O_2, since this was the sole reducible species present in solution (Figure 4c and 4d,

432   respectively). Due to the electrode rotation, the current increased until a limiting value (I_{lim}) was

433   attained, which depended primarily on the electrode ω, the dissolved O_2 concentration (C_{O_2}), the

434   O_2 diffusion coefficient (D_{O_2}), the solvent kinematic viscosity (v) and the number of transferred

435   electrons (n), according to the Koutecky–Levich equation:[12]

436   $$\frac{1}{I} = \frac{1}{I_k} + \frac{1}{I_{lim}} = \frac{1}{nFAkC_{O_2}} + \frac{1}{0.62nFA(D_{O_2})^{2/3}v^{-1/6}C_{O_2}\omega^{1/2}} \qquad (10)$$

437   where I_k is the kinetic current and I_{lim} is the diffusion limiting current. In such setup, the electrode

438   rotation pushes the electrogenerated species toward the ring electrode, which is polarized at a fixed

439   potential (E_{ring} = 1.50 V vs. RHE), at which H_2O_2 can be easily reoxidized to H_2O. If H_2O_2 is

440   generated at the disk electrode, it can then be detected at the ring electrode and a ring current (I_R)

441   can be recorded in the case of MC-C and N-MC-C (Figure 4c' and 4d', respectively). The number

442   of exchanged electrons can be in principle be determined by plotting the reciprocal of the total

443   instant current (I^{-1}) versus $\omega^{-1/2}$, whenever all the other specific parameters are known. However,

444   this procedure can bring to misleading results when, for example, the catalyst layer is not

445   homogeneous and sufficiently thin. Alternatively, the number of electrons involved in the ORR

446   and the yield of hydrogen peroxide ($y_{H_2O_2}$) can be obtained from the I_D (in A) and I_R (in A) values

447   measured at the RRDE, according to Eqs. (11) and (12):[72]

448
$$n = \frac{4I_D}{I_D + {I_R}/{N}} \tag{11}$$

449
$$y_{H_2O_2} = 100 \frac{2I_R}{NI_D + I_R} \tag{12}$$

450   where N is the collection efficiency (N = 0.25). The half-wave potential, which can be determined

451   from the RRDE measurements, confirmed the higher catalytic activity of N-MC-C ($E_{1/2}$ = 0.437

452   V) as compared to MC-C ($E_{1/2}$ = 0.288 V). Furthermore, the n values were 3.55 and 3.76, using

453   N-MC-C and MC-C, respectively, which informs about the superior selectivity versus H_2O_2

454   generation using the former electrode. In fact, the hydrogen peroxide yields ($y_{H_2O_2}$, Figure 4c''

455   and 4d'') were 25% (N-MC-C) and 11% (MC-C). At first sight, these values could seem to far

456   from n = 2 and $y_{H_2O_2}$ = 100% ideally expected from an electrocatalyst that fully promotes the two-

457   electron ORR, without further H_2O_2 reduction or simultaneous reaction (5). Nonetheless, the main

458   goal within the context of this work was not the development of an optimum electrocatalyst for

459   H_2O_2 electrosynthesis, but the synthesis of a potentially cheaper and more eco-friendly material to

460   electrogenerate sufficient amounts of H_2O_2 for its direct application in Fenton-based

461   electrochemical water treatments. Therefore, bulk electrolyses were conducted in order to assess

462   the ability of GDEs, prepared with the synthesized MC-C and N-MC-C, to accumulate H_2O_2.

A series of long galvanostatic electrolyses was carried out, at different current densities from 10 to 60 mA/cm^2, to monitor the concentration of H_2O_2 accumulated in a 0.050 M Na_2SO_4 solutions at pH 3.0 for 360 min. In these trials, either an MC-C- or N-MC-C-derived GDE was connected to a DSA plate. As can be seen in Figure 5a, with both types of GDE, a higher concentration was achieved as the electrolysis progressed, as a result of the effective ORR via reaction (1). However, the initially linear trends became curves after 120-180 min, which means that the processes that accounted for the H_2O_2 destruction gradually became more significant. The main ones among them were: (i) the cathodic reduction via reaction (6), (ii) its oxidation at the anode surface, since the cell had one single compartment, and (iii) the chemical decomposition and natural disproportionation in the bulk. In fact, a final plateau could be observed in some cases, especially at the highest current density of 60 mA/cm^2, which was reached once the H_2O_2 formation and destruction rates became equal. At 360 min, the concentrations attained at 10, 30 and 60 mA/cm^2 were 3.68, 9.35 and 9.75 mM using the MC-C, and 5.20 13.2 and 15.3 mM with the N-MC-C. Therefore, the greatest values appeared in the cells with the N-MC-C-derived GDE, regardless of the applied current density, which confirms the importance of the superficial N content and the corresponding N-functionalities described above. Furthermore, the difference was higher as the current density was increased (i.e., the curves with both GDEs were comparatively more separated), suggesting a relatively greater stability of the N-MC-C under more aggressive conditions. In fact, using the MC-C-derived GDE, the H_2O_2 contents at 30 and 60 mA/cm^2 were very close, meaning that the stability range for that cathode was more limited. Such lower stability can be related to its structural characteristics, discussed above, since a lower porosity and greater compactness constitute a barrier that oxygen gas tends to break in a rough manner.

A comparison with reported values for H_2O_2 accumulation in similar setups that employed commercial C-PTFE GDEs allows concluding that the electrogeneration performance observed in this work is in the same range, in particular in the case of the GDE prepared with the N-MC-C.

488 For example, 0.59 mM H_2O_2 (vs 2.00 mM in this work) were measured at 30 min in a 0.050 M

489 Na_2SO_4 solution at pH 3.0 recirculated at a liquid flow rate of 4.4 L/min and electrolyzed at 30

490 mA/cm^2 in a pilot plant, whereas a content of 17 mM H_2O_2 was achieved after 360 min at 50

491 mA/cm^2 in a 2.5 L plant.[78] Moreover, the values represented in Figure 5a are much better than

492 those typically attained with raw carbon-felt cathodes, which have also been employed in EF and

493 PEF treatments.[5] These results corroborate that the electroactivity of the synthesized catalysts was

494 high enough to accumulate H_2O_2, despite the partial selectivity discussed from Figure 4. For a

495 more accurate comparison with the literature, Table S2 summarizes the current efficiency, H_2O_2

496 mass production rate and H_2O_2 yield calculated for our best catalyst as well as for carbon

497 electrocatalysts employed in GDEs for water treatment. Note that, despite the moderate efficiency

498 of the new material to accumulate H_2O_2, the crucial finding of this work is that the electrogenerated

499 amount is sufficient to promote the degradation of water pollutants (see subsections below).

500   The presence of Fe^{2+} in the solution (i.e., EF conditions) should cause a drastic reduction in

501 the quantity of H_2O_2 accumulated due to its quick decomposition via Fenton's reaction (2). Indeed,

502 this is verified in Figure 5b, which shows similar profiles regardless of the type of cathode when

503 Fe^{2+} at a concentration of 0.50 mM was employed as catalyst. The other conditions were analogous

504 to those described in Figure 5a, at 30 mA/cm^2. Based on the almost identical trends to finally attain

505 a value of ~5.1 mM H_2O_2, and considering that the N-MC-C-derived GDE was proven to generate

506 more H_2O_2 than the MC-C GDE in the absence of Fe^{2+} (Figure 5a), a greater $^{\bullet}OH$ production can

507 be inferred. This should entail a faster water decontamination, as will be discussed later. The result

508 obtained in these EF systems is in good agreement with that previously reported with a commercial

509 GDE in an analogous solution (< 10 mM H_2O_2 at 30 mA/cm^2).[79] Similar experiments were made

510 exposing solutions with the same composition to UVA photons (PEF conditions), which caused

511 an additional reduction in the content of the oxidant accumulated at each electrolysis time until

512 reaching ~4.6 mM H_2O_2 at 360 min (Figure 5b). This is explained by the occurrence of photo-

21

513   Fenton reaction (3), with optimum $\lambda = 360$ nm. The continuous Fe^{2+} photo-induced regeneration

514   sustained the Fenton's reaction (2), which otherwise would be mitigated due to the gradual

515   conversion of Fe^{2+} into the much less active species $[Fe(OH)]^{2+}$ (i.e., the main Fe(III) species at

516   pH 3.0).[5]

517   The current efficiencies for all the trials depicted in Figure 5a and 5b, determined from Eq.

518   (4), are illustrated in Figure S4a and S4b, respectively. In all cases, a loss of efficiency over time

519   can be observed, in agreement with the progressively lower H_2O_2 accumulation rate (i.e., the

520   curvature appearance after some minutes in Figure 5 owing to parasitic reactions). In the absence

521   of Fe^{2+} (Figure S4a), the maximum efficiency of ~40% (reasonably good taking into account that

522   the cell was undivided) corresponded to the treatment with N-MC-C at 10 mA/cm^2. Worth

523   noticing, upon increase to 30 mA/cm^2 the efficiency profile was very similar, which is interesting

524   in practice to promote a faster degradation. Therefore, this current density was selected as optimum

525   for subsequent trials. When the current density was then doubled, the efficiency was almost halved,

526   confirming the detrimental enhancement of parasitic destruction reactions (i.e., cathodic and

527   anodic phenomena mentioned before). All the treatments with the MC-C-derived GDE were much

528   less efficient ($<$ 25% during all the electrolysis). As expected from the practically overlapping

529   H_2O_2 profiles found in EF and PEF (Figure 5a), Figure S4b evidences similar trends for the

530   corresponding current efficiencies (always lower than 20%), with slightly higher values in EF

531   assays.

532   **Degradation of acebutolol using GDEs prepared with the synthesized catalysts.** For the

533   dual purpose of assessing the viability of the new GDEs to foster the degradation of organic

534   pollutants and confirming the superiority of N-MC-C electrocatalyst, solutions containing 0.046

535   mM of the β-blocker acebutolol and 0.050 M Na_2SO_4 at pH 3.0 were electrolyzed at the optimized

536   current density (30 mA/cm^2). In Figure 6a, the drug concentration decays under electro-oxidation

537   (EO-H_2O_2) conditions with each GDE. The degradation was quite slow in both cases, ending in

modest removals of 35% and 51% at 180 min using the MC-C- and N-MC-C-derived GDE, respectively. Since H_2O_2 behaves as a rather mild oxidant in front of aromatic structures like that exhibited by acebutolol, within the concentration ranges as that discussed from Figure 5a,[6] the partial drug disappearance can be attributed to the action of hydroxyl radicals M($^\bullet$OH) formed on the anode (M) surface from reaction (13).[40,48] The data could not be fitted well considering a simple kinetic model, thus suggesting a larger complexity due to the influence of reaction products.

$$M + H_2O \rightarrow M(^\bullet OH) + H^+ + e^- \tag{13}$$
The degradation was drastically upgraded in the presence of 0.50 mM Fe^{2+} and UVA photons under PEF conditions, as evidenced in Figure 6b. The use of the two DSA/GDE cells led to 97% and 100% acebutolol removal in only 20 min using the MC-C and N-MC-C electrocatalyst, respectively. Such significant acceleration of concentration decays was pre-eminently favored by the generation of $^\bullet$OH upon fast decomposition of H_2O_2 via Fenton's reaction (2), which confirms the explanation given on the time course of H_2O_2 (Figure 5b). The effective $^\bullet$OH production was ensured by the continuous Fe(III) photoreduction from reaction (3), which yielded additional amounts of $^\bullet$OH and regenerated the Fe^{2+}. The replacement of the RuO_2-based anode by BDD had a positive influence on the destruction of the pollutant, being more evident in the system with N-MC-C, since the complete disappearance was observed at 16 min. Using MC-C, almost no change in degradation percentage (98%) was reached, but the initial concentration decay became quicker. This is clear in the inset of Figure 6b, which depicts the excellent linear fitting ($R^2 > 0.990$) resulting from a pseudo-first-order kinetic analysis of all decays of the main figure. The pseudo-first-order rate constant (k_1) increased from 0.1748 to 0.2296 min^{-1} when the anode was changed to BDD in the system with MC-C. Accordingly, higher k_1-values were determined using N-MC-C, namely 0.2583 and 0.3258 min^{-1} with DSA and BDD, respectively. The enhancement achieved with BDD anode is associated to the physisorbed nature of M($^\bullet$OH) produced from reaction (13), which makes the radicals more reactive with organic molecules approaching its surface.[48]

23

However, it is clear that the main factors affecting the drug degradation were those related with the Fenton's reactivity, as can be deduced when comparing Figure 6a and 6b. Among such factors, the benefit of the higher H_2O_2 electrogeneration with N-MC-C stands out.

The performance of our biomass-derived GDEs is comparable to that reported for GDEs prepared with carbon cloth coated with commercial carbon black. For example, the treatment of β-blocker atenolol in 0.050 M Na_2SO_4 at pH 3.0 by PEF at 16.7 mA/cm^2 allowed the total drug removal in 30-35 min, with $k_1 = 0.05$ min^{-1}, thus being in the same order of magnitude.[80]

Figure 7 highlights the time course of normalized TOC content with electrolysis time during the PEF assays of Figure 6b. Unlike that observed in the previous HPLC analysis, the effect of the anode nature was crucial to upgrade the mineralization of the solutions, which initially contained 10 mg/L TOC. Partial TOC abatements were obtained with DSA, attaining 71% and 76% at 360 min using MC-C and N-MC-C, respectively. A much greater decontamination was feasible upon use of BDD anode, with final values of 91% and 97%. In all these systems, the effective generation of •OH in the bulk sustained by reaction (3) undoubtedly contributed to the gradual degradation of reaction products. However, this was insufficient because it is known that the aromatic molecules are transformed into very refractory aliphatic products and their complexes with Fe(III) that resist quite well the attack of •OH.[3,4] Therefore, UVA photons played an additional role, allowing the photodecarboxylation of such stable complexes:

$$[Fe(OOCR)]^{2+} + h\nu \rightarrow Fe^{2+} + R^\bullet + CO_2 \qquad (14)$$
As inferred from both PEF trials with DSA, the degradation power of •OH and UVA light was still limited and hence, M(•OH) formed at BDD favored the electrocatalytic destruction of the refractory molecules. As a result, the combination of the most effective anode and cathode yielded the greater mineralization. Note that TOC decays reported for acebutolol solutions through other advanced oxidation processes were lower, as in the case of photocatalysis with TiO_2 with 75% mineralization at 240 min.[81]

24

The following overall mineralization reaction can be proposed, based on the determination of inorganic ions discussed below:[5]

$$C_{18}H_{28}N_2O_4 + 32H_2O \rightarrow 18CO_2 + 2NH_4^+ + 84H^+ + 86e^- \qquad (15)$$
From Eq. (5), in which the total number of electrons involved was $n = 86$, the MCE values calculated at a given electrolysis time for the assays of Figure 7 are represented in Figure S5a. The most efficient process was PEF with the BDD/GDE cell using N-MC-C, in agreement with the effective TOC removal in that system. Nonetheless, the fact that the maximum MCE was < 15% reflects the high refractoriness of the pollutant and its derivatives. As the treatments progressed, a loss of efficiency was observed, meaning that the organic structures and complexes formed were more resistant to $^\bullet OH$, $M(^\bullet OH)$ and UVA photons than the target pollutant and its primary intermediates. In addition, the side reactions that wasted the radicals and photons occurred to a greater extent as the number of available organic molecules decreased. These two phenomena with negative impact on the process efficiency were also detrimental in terms of energy consumption. The EC_{TOC} values calculated from Eq. (6) and represented in Figure 6b were higher in trials with BDD, which is mainly explained by the much greater E_{cell} as compared to those with the RuO_2-based anode (15.5 vs 8.0 V, regardless of the GDE). Note that these energy consumptions are purely electrolytic. If the lamp consumption is added (i.e., the term $E_{cell}I$ in Eq. (6) is replaced by the lamp power to determine $(EC)_{photo}$),[82] the EC_{TOC} values increase up to ~30 and ~36 kWh / g TOC using BDD and DSA, respectively. In practice, natural sunlight can be used instead artificial UVA light, thus avoiding the large contribution of $(EC)_{photo}$.

In Figure 8a-d, the SEM images of GDEs prepared with both chitosan-based electrocatalysts can be seen at two different magnifications. A good surface coverage of carbon cloth was obtained with MC-C and N-MC-C, with no evidence of exposed carbon fibers. This is attributed to the good spraying procedure, giving rise to several layers, followed by hot pressing. Some gaps can be appreciated, which are better identified at the highest magnification (Figure 8b and 8d). These

613   macropores favored the mass transport rate of O_2 toward the catalytic sites.[5] Amorphous particles

614   with dimensions of some microns appear in both types of GDE, as is typical for C-PTFE GDEs.

615   Some of them formed clusters wrapped around the fibers (Figure 8b). PTFE, recognized as the

616   white spots, was spread over the surface, conferring sufficient hydrophobicity to the materials.

617   Note that no flooding of the GDEs was observed during the trials of this work. The GDEs used in

618   PEF treatments with DSA described in Figure 7 were collected at the end of the electrolyses. The

619   corresponding SEM analysis (Figure 8a'-d') at the same magnifications mainly show smoother

620   surfaces without clear distinction of carbon particles and, more important, the obvious presence of

621   uncoated or partially coated fibers. This phenomenon was more evident in the cathode prepared

622   with MC-C, which can be directly explained from its aforementioned lower stability. Oxygen gas

623   is forced through its compact structure, causing a partial disintegration. However, this did not

624   impede to reuse all the GDEs for several consecutive runs without any substantial loss of

625   performance related to H_2O_2 production and degradation ability.

626   **Reaction products identified during the PEF treatment of acebutolol solutions.** In the

627   previous subsection, the TOC-time and MCE-time profiles have been justified on the basis of the

628   different reactivity of the reaction products. To demonstrate this, a 0.046 mM acebutolol solution

629   with 0.050 M Na_2SO_4 and 0.50 mM Fe^{2+} at pH 3.0 was treated by PEF for 60 min, using a cell

630   with the RuO_2-based anode connected to a GDE made with N-MC-C catalyst, at 30 mA/cm^2.

631   Samples collected at 10 and 60 min and analyzed by GC/MS revealed the presence of six aromatic

632   and three nitrogenated aliphatic compounds, whose characteristics are summarized in Table S3. In

633   Figure 9, the generation of these molecules is proposed considering the modification of parts R1,

634   R2, R3 and R4 distinguished in acebutolol. Some authors detected a product similar to **2**, but

635   hydroxylated in C1 position, when acebutolol solutions were treated by droplet-assisted

636   heterogeneous EF.[83] They also identified a structure close to **6** but keeping R1, and another one

637   like **7** but non-hydroxylated.

638   Most of these nine products were expected to be gradually hydroxylated.[5] Therefore, the

639   evolution of the concentration of short-chain linear carboxylic acids during the same kind of PEF

640   treatment was investigated. Figure 10 evidences the trends of oxalic acid, whose peak was found

641   at retention time of 7.0 min, and oxamic acid, which appeared at 9.8 min. The former attained a

642   maximum concentration of 1.75 mg/L at 30 min, quickly decaying to finally disappear at 120 min.

643   Oxalic acid is a typical end organic product from aromatic pollutants, which is the reason that

644   explains that it was the main accumulated carboxylic acid.[51] The high photoactivity of its

645   complexed form under UVA light according to reaction (14) justifies its total degradation in PEF.

646   In contrast, oxamic was only formed from larger N-structures, reaching a lower content of 1.05

647   mg/L at 60 min. Moreover, since it formed much less photoactive complexes,[51] it persisted in the

648   solution during the entire electrolysis. The presence of both acids as acebutolol is degraded has

649   also been reported elsewhere.[83]

650   The inorganic ions generated in PEF treatment from the heteroatoms contained in the drug

651   were determined as well. A more concentrated acebutolol solution (i.e., 0.092 mM) was employed

652   in order to facilitate the quantification. Neither nitrite nor nitrate were identified, being NH_4^+ the

653   only dissolved nitrogenated ion detected, thus corroborating the validity of mineralization reaction

654   (15). The ammonium content increased all the time, as the organic N-structures were degraded,

655   attaining 1.43 mg/L at 360 min. This cation was also the main nitrogenated ion found during the

656   degradation of other N-aromatic pollutants by Fenton-based electrochemical processes.[70] A

657   nitrogen balance after normalizing the acebutolol content suggests that the treated solutions

658   contained ~50% of initial dissolved nitrogen, most of it corresponding to NH_4^+. This means that

659   some N-containing gases were released during the PEF treatment of acebutolol.

27

CONCLUSIONS

This work reports the successful synthesis and characterization of a potentially cheaper and more eco-friendly material to electrogenerate sufficient amounts of H_2O_2 for its direct application in Fenton-based electrochemical water treatment. Chitosan was considered as raw material for the preparation of N-doped carbon. It was observed that the addition of 1,10-phenathroline as co-reactant during the pyrolysis treatments conferred better textural properties and surface N-functionalization than the sole chitosan. LSV at RRDE highlighted the higher catalytic activity of N-MC-C, in terms of $E_{1/2}$. GDEs prepared with N-MC-C showed H_2O_2 yields in the same range attainable with commercial GDE. The degradation of 0.046 mM acebutolol solutions was made with the N-MC-C-derived GDE coupled to a RuO_2-based anode in an electrochemical cell at pH 3.0. The PEF assays in such cell resulted in a fast and complete drug removal. The use of BDD instead of DSA had a positive influence on the decontamination, since the almost complete TOC removal was achieved at the end of the electrolysis. GC/MS analysis clarified the main aromatic and aliphatic products formed during the mineralization process. Short-chain linear carboxylic acids such as oxalic and oxamic were generated as final organic compounds, whereas NH_4^+ was the main ion.

Figure captions

Figure 1. Different stages during the synthesis of MC-C catalysts: (a) chitosan viscous solution, (b) hydrogel coagulation (c) chitosan hydrogel, (d) hydrogel after freeze drying, (e) dried hydrogel after pyrolysis at 400 °C, (f) first pyrolysis product after milling, (g) product after pyrolysis at 900 °C.

Figure 2. TEM images of (a-c) MC-C and (d-f) N-MC-C catalysts.

Figure 3. (a) Nitrogen adsorption/desorption isotherms of MC-C and N-MC-C catalysts; (b) Raman spectra for both materials; C 1s XPS core-level spectra for (c) MC-C and (d) N-MC-C catalysts; N 1s XPS core-level spectra for (e) MC-C and (f) N-MC-C. In plot (c-f), deconvolution signals are also shown.

Figure 4. Electrochemical data for the investigated materials, drop-cast on glassy carbon (catalyst loading: 0.3 mg/cm^2), in Ar-purged and O$_2$-saturated 0.0005 M H$_2$SO$_4$ + 0.050 M Na$_2$SO$_4$ electrolyte. Cyclic voltammograms using (a) MC-C and (b) N-MC-C, at v_{scan} = 20 mV/s. Linear sweep voltammograms at RRDE, with at v_{scan} = 10 mV/s and ω = 1600 rpm, using (c) MC-C and (d) N-MC-C. (c', d') Ring current, at E_{ring} = 1.50 V vs. RHE, and (c", d") H$_2$O$_2$ selectivity during the linear sweep voltammetry in O$_2$-saturated electrolyte, using (c', c``) MC-C and (d', d") N-MC-C.

Figure 5. Evolution of H$_2$O$_2$ concentration during the electrolysis of 150 mL of 0.050 M Na$_2$SO$_4$ solutions at pH 3.0 and 25 °C, using a cell with the MC-C or N-MC-C cathode and a DSA plate as the anode at different current densities and air flow rate of 36 L/h. Process: (a) EO-H$_2$O$_2$, and (b) EF with 0.50 mM Fe^{2+} and PEF with 0.50 mM Fe^{2+} and a 6 W UVA lamp.

Figure 6. Time course of acebutolol concentration during the treatment of 150 mL of solutions with 0.046 mM drug and 0.050 M Na$_2$SO$_4$ at pH 3.0 and 25 °C, using a cell with the MC-C or N-

MC-C cathode at a current density of 30 mA/cm^2 and air flow rate of 36 L/h. Process (a) EO-H$_2$O$_2$ with DSA, and (b) PEF with 0.50 mM Fe^{2+}, a 6 W UVA lamp and DSA or BDD as the anode. In (b), the inset panel presents the corresponding pseudo-first-order kinetic analysis.

Figure 7. Change of normalized TOC with electrolysis time for the PEF trials shown in Fig. 6b.

Figure 8. SEM images of GDEs prepared with the chitosan-based electrocatalysts. (a-d) Fresh and (a'-d') used. Magnification: (a,a',c,c') 100× and (b,b',d.d') 500×. The used GDEs were those collected at the end of the PEF treatments with DSA described in Fig.7.

Figure 9. Primary products of acebutolol during PEF treatment with chitosan-derived electrocatalysts.

Figure 10. Evolution of the concentration of aliphatic carboxylic acids during the PEF treatment of 0.046 mM acebutolol solutions with 0.050 M Na$_2$SO$_4$ and 0.50 mM Fe^{2+}, as well as NH$_4^+$ content accumulated during an analogous treatment but using 0.092 mM drug and 0.020 M Na$_2$SO$_4$ instead. Conditions: cell with N-MC-C cathode (fed with air at 36 L/h) and the RuO$_2$-based anode, containing 150 mL of solutions at pH 3.0 and 25 ºC exposed to a 6 W UVA lamp and electrolyzed at 30 mA/cm^2.
