13 14 **Abstract**

15 New Barremian–early Aptian charophyte biozonations are proposed here based on
16 the charophyte succession in the Maestrat Basin (Iberian Chain, Spain). Biostratigraphic
17 analysis distinguished two biozonations, European and Eurasian, which were compared
18 to establish correlations. This is the first time that Early Cretaceous charophyte biozones
19 are calibrated by means of strontium-isotope stratigraphy, enabling their correlation
20 with the coeval marine realm (ammonite biostratigraphy). The European charophyte
21 biozonation is formed of two partial range biozones, whose index species were endemic
22 from the Cretaceous Tethyan Archipelago (present-day Europe and Northern Africa):
23 (1) *Globator maillardii* var. *trochiliscoides* (early Barremian) and (2) *Asciadiella*
24 *cruciata*-*Pseudoglobator paucibracteatus*. The base of the *A. cruciata*-*P. paucibracteatus*
25 biozone was calibrated with an oyster shell sample whose ⁸⁷Sr/⁸⁶Sr is 0.707482,
26 translating to a late early Barremian age. The total time span of this latter biozone is late
27 early Barremian–early Aptian. The Eurasian biozonation involves a novel Lower

28 Cretaceous charophyte biostratigraphy. It has more resolution than the European
29 biozonation, as it is composed of three partial range biozones whose index species were
30 well-distributed in Eurasia. From oldest to youngest these are: (1) *Atopochara trivolv*
31 *var. triquetra*, (2) *Hemiclavator neimongolensis var. neimongolensis*, and (3) *Clavator*
32 *grovesii var. jiuquanensis*. The *A. trivolv* *var. triquetra* biozone characterises the early
33 Barremian, being almost equivalent to the European *G. maillardii var. trochiliscoides*
34 biozone. The base of the *H. neimongolensis var. neimongolensis* biozone is marked by
35 the first appearance datum (FAD) of *Hemiclavator neimongolensis var. neimongolensis*
36 and was calibrated with an oyster shell whose $^{87}\text{Sr}/^{86}\text{Sr}$ is 0.707481 corresponding to a
37 late early Barremian age. The top of the *H. neimongolensis var. neimongolensis* biozone
38 coincides with the FAD of *Clavator grovesii var. jiuquanensis*. The base of the *C.*
39 *grovesii var. jiuquanensis* biozone was dated with an oyster sample sample collected 25
40 m below the FAD of *C. grovesii var. jiuquanensis*. The $^{87}\text{Sr}/^{86}\text{Sr}$ value of this sample is
41 0.707489, which translates into an early late Barremian age. Thus, the *H.*
42 *neimongolensis var. neimongolensis* biozone spans the late early Barremian-early late
43 Barremian interval. The top of the *Clavator grovesii var. jiuquanensis* biozone (late
44 Barremian–early Aptian) is marked by the FAD of *Clavator grovesii var. lusitanicus*.
45 The newly proposed Eurasian charophyte biozonation will facilitate the correlation
46 between non-marine basins in one of the largest continental areas on Earth.

50

51 **1. Introduction**

52 The fructifications (utricles) of the fossil charophyte family Clavatoraceae are
53 widely used for the biostratigraphic characterisation of continental Late Jurassic-Early

54 Cretaceous successions (e.g., Grambast 1974, Wang and Lu 1982, Mussacchio 1989,
55 2000, Schudack 1987, 1993, Martín-Closas 1989, Martín-Closas and Alonso-Millán
56 1998, Feist et al. 1995, Trabelsi et al. 2016). A number of Barremian-lower Aptian
57 charophyte biozonations have been proposed in Europe (e.g., Grambast 1974; Feist et
58 al. 1995, Riveline et al. 1996, Mojon 1996, 2002) and China (e.g., Wang and Lu 1982,
59 Peng et al. 2003, Yang et al. 2008). Despite the extensive work carried out on
60 clavatoracean biostratigraphy in Europe and Asia, the different biozones proposed have
61 not been numerically dated or correlated between continents. The relative ages of
62 previous proposals were determined from the correlation with foraminifera found in
63 marine deposits, which occur interbedded within continental successions (e.g., Combes
64 et al. 1966, Martín-Closas and Salas, 1988, 1994, Mojon 2002, Martín-Closas et al.
65 2009). Li et al. (2020) dated charophyte assemblages from Chinese basins to the late
66 Barremian-early Aptian time by using previously published chemostratigraphic data and
67 by considering the age assigned to similar charophyte assemblages in European basins.

68 In Europe, two Barremian biozones were first proposed by Grambast (1974)
69 spanning the early Barremian and the late Barremian, respectively. These biozones were
70 the bases for the later proposals (e.g., Feist et al. 1995, Mojon 1996). The most used
71 present-day European Barremian biozonation was proposed by Riveline et al. (1996)
72 and later modified by Martín-Closas et al. (2009). These authors used assemblages and
73 ages similar to those reported by Grambast (1974).

74 In Asia, different charophyte biostratigraphic charts have been proposed for the
75 Chinese basins. Wang and Lu (1982) defined two biozones that have Hauterivian-early
76 Barremian and late Barremian age ranges, respectively. Later on, Peng et al. (2003)
77 combined these two biozones into a single biozone spanning the whole Barremian, and
78 Yang et al. (2008) considered this latter biozone to also span the Hauterivian Stage.
79 This relatively low-resolution charophyte biostratigraphy contrasts with the proposals

80 for other Cretaceous stages whose time span is similar to that of the Barremian. This is
81 the case, for example, with the late Campanian-late Maastrichtian European and Asian
82 charophyte biostratigraphy that involve three biozones (e.g., Vicente et al. 2015, Li et
83 al. 2019).

84 This paper presents new European and Eurasian charophyte biostratigraphic
85 frameworks for the Barremian-early Aptian, based on the clavatoracean succession
86 identified in the Maestrat Basin (Iberian Chain, Spain) and the extensive data on
87 clavatoracean biogeography available for this time span elsewhere (e.g., Martín-Closas
88 and Wang 2008, Martín-Closas 2015, Pérez-Cano et al. 2020). The analysis of this
89 charophyte record along with a continuous Barremian succession enabled us to
90 determine the first appearance datum (FAD) of several species from the Barremian,
91 improving the resolution of the Barremian biostratigraphy. Moreover, the identification
92 of the FAD of Eurasian-distributed taxa (i.e., *Atopochara trivolvris* var. *triquetra*,
93 *Clavator grovesii* var. *jiuquanensis*, *C. harrisii*, *C. calcitrapus*, and *Hemiclavator*
94 *neimongolensis* var. *neimongolensis*; Martín-Closas and Wang 2008, Martín-Closas
95 2015) enabled their use as index species, improving the correlation between Europe and
96 Asia.

97 The utility of a biostratigraphic framework increases when it is faithfully
98 calibrated to a time scale. Charophyte biozonations from other ages have been
99 calibrated against the Geomagnetic Polarity Time Scale (GPTS), which translates into
100 numerical ages. This has been performed for the Campanian–Danian charophyte
101 biozonations of the Pyrenees (Galbrun et al. 1993, Vicente et al. 2015) and the Chinese
102 basins (Li et al. 2016, 2019), as well as for the Eocene biozonation of the Ebro Basin
103 (Sanjuan et al. 2014). However, the calibration of Late Jurassic-Early Cretaceous
104 charophyte biozones in southern European basins with the GPTS is not straightforward
105 due to the Alpine Orogeny-related remagnetisation of the Mesozoic record (e.g.,

106 Moreau et al. 1992, Gong et al. 2009). Consequently, the calibration of the Barremian-
107 early Aptian biostratigraphy presented here was performed by numerically dating
108 marine intercalations using strontium isotope stratigraphy (SIS), a methodology
109 extensively used for the calibration of marine records (e.g., Steuber 1999, Williamson et
110 al. 2012, Frijia et al. 2015, Bover-Arnal et al. 2016, Caus et al., 2016).

111

112 **2. Geological setting**

113 The Maestrat Basin was part of an intracratonic rift system that developed in the
114 NE part of the Iberian plate (Fig. 1A–B) during the Mesozoic as a consequence of the
115 breakup of Pangaea and the opening of the Central Atlantic Ocean (Salas and Casas
116 1993, Salas et al. 2001). According to Salas et al. in Martín-Chivelet et al. (2019), there
117 were three different stages of rifting followed by three post-rift phases in the Iberian rift
118 system: (1) Late Permian–Triassic rifting, (2) Early–Middle Jurassic post-rift, (3) Late
119 Jurassic–middle Berriasian rifting, (4) late Berriasian–Hauterivian post-rift, (5)
120 Barremian–early Albian rifting and (6) Late Cretaceous post-rift. The Maestrat Basin is
121 associated with the Late Jurassic–middle Berriasian and the Barremian–early Albian
122 rifting stages. Listric extensional faults and palaeotopographic highs subdivided the
123 basin into several sub-basins, from north to south, namely El Perelló, Morella, Oliete,
124 Las Parras, Galve, Salzedella, Orpesa, Penyagolosa and Cedramán, with different
125 subsidence rates and sedimentary features (Fig. 1B; Salas and Guimerà 1996, Salas et
126 al. in Martín-Chivelet et al. 2019). The study areas are located within the Morella Sub-
127 basin (Fig. 1B–D). The sedimentary deposition in this sub-basin ranged from non-
128 marine carbonate successions, mainly found along the northern margin of the half-
129 graben, to hemipelagic successions occurring in the central zone of the sub-basin
130 (Canérot et al. 1982, Salas 1987). Later, during the Alpine orogeny (Late Cretaceous–

131 early Miocene), the Iberian rift system was inverted to form the Iberian Chain (Nebot
132 and Guimerà 2016, Guimerà 2018).

133

134 -----Please insert Fig. 1 near here-----

135

136 The Barremian sedimentary record of the Morella Sub-basin is subdivided into
137 five formations: Cantaperdius, Artoles, Morella, Cervera del Maestrat and Xert (Fig. 2;
138 Canérot et al. 1982, Salas 1987, Salas et al. 2001, Bover-Arnal et al. 2016). The present
139 study was carried out along the Cantaperdius, Artoles and Morella formations (Fig. 2).
140 The non-marine lacustrine Cantaperdius Formation is mainly composed of alternating
141 charophyte-rich marls and limestones. It is up to 400 m-thick in the northern area of the
142 Morella Sub-basin and becomes thinner towards the central part of the basin, where it
143 laterally changes into the Artoles Formation. The Artoles Formation, which also
144 overlies the Cantaperdius Formation throughout the sub-basin, is characterized by
145 coastal to shallow open marine marls and limestones rich in oysters (Salas 1987, Salas
146 et al. 2001, Bover-Arnal et al. 2016). This unit is up to 700 m thick in the central parts
147 of the sub-basin, with its thickness decreasing to less than 200 m in the marginal areas.
148 Laterally and above the Artoles Formation, there is the Morella Formation, a non-
149 marine unit composed of grey to red and purple clays and sandstones (Canérot et al.
150 1982, Salas, 1987, Gámez et al., 2003). Towards the depocentre of the sub-basin, the
151 Morella Formation becomes progressively more brackish-influenced, laterally passing
152 to the Cervera del Maestrat Formation that contains mixed carbonate-siliciclastic coastal
153 and shallow marine deposits (Canérot et al. 1982, Salas, 1987, Salas et al. 2001). The
154 Xert Formation corresponds to a fully marine succession composed of marls and
155 limestones rich in orbitolinids. The Morella, Cervera del Maestrat and Xert formations

156 have been dated to the late Barremian using ammonites and SIS (García et al. 2014,
157 Bover-Arnal et al. 2016).

158

159 -----Please insert Fig. 2 near here-----

160

161 **3. Palaeobotanical setting**

162 Since the middle of the 20th century, the taxonomic studies carried out by Louis
163 Grambast (Grambast 1966a, b, 1967, 1968, 1969, 1970, 1974) and later continued by
164 Martín-Closas and Grambast-Fessard (1986), Martín-Closas (1989, 2000), Schudack
165 (1993), Climent-Domènech et al. (2009) and Pérez-Cano et al. (2020) have illustrated
166 the high biodiversity of the charophytes occurring in the Lower Cretaceous non-marine
167 record of the Maestrat Basin. These studies showed that the extinct Clavatoraceae
168 family dominated the non-marine settings of the basin during that period. The
169 stratigraphic continuity of the non-marine record of the Maestrat Basin provides an
170 excellent context to understand the evolution and phylogeny of the clavatoracean
171 species, enabling the identification of evolutionary lineages with biostratigraphic
172 significance (Grambast, 1966a, 1968, 1974; Martín-Closas, 1989, 1996, 2000). The
173 species identified in the studied sections are summarised in Table 1 and shown in Plates
174 1 and 2.

175 -----Please insert Table 1 near here-----

176

177 **4. Materials and methods**

178 **4.1. Lithostratigraphy and charophyte sampling**

179 Two Barremian sections from the Morella Sub-basin were logged and
180 systematically sampled for the identification of charophyte assemblages: Herbers-Mas
181 de Petxí (base: 40°42'39"N, 0°0'36"W; top: 40°42'34"N, 0°0'30"E) (Figs. 1C and 3A–

182 B) and Fredes (base: 40°41'20.71"N, 0°10'1.25"E; top: 40°41'27.09"N, 0°9'54.44"E)
183 (Figs. 1D and 4). Samples of approximately 3 kg were taken from each marl or clay
184 bed. In the laboratory, the samples were disaggregated using a solution of water, sodium
185 carbonate (Na₂CO₃; useful for deflocculating the clay), and hydrogen peroxide (H₂O₂;
186 eliminates the organic matter and helps with the disaggregation). These samples were
187 left for a few days and then sieved through meshes with apertures of 1, 0.5, and 0.2 mm.
188 When the samples were dried, charophyte fructifications were handpicked using a Wild
189 M5A binocular microscope. The fructifications were measured using a Motic BA310
190 microscope and the Motic Images Plus 2.0 software. Selected specimens were studied
191 and photographed with a Quanta 200 Scanning Electronic Microscope (SEM) at the
192 Centres Científics i Tecnològics de la Universitat de Barcelona (CCiTUB). The figured
193 specimens were deposited at the Museu de Geologia del Seminari Conciliar de
194 Barcelona (MGSCB). The handpicked material has been kept at the Departament de
195 Dinàmica de la Terra i de l'Oceà of the Universitat de Barcelona.

196 Limestone beds were also sampled and studied as *c.* 30 µm-thick sections cut
197 parallel and perpendicular to the bedding surface of the sample. These sections were
198 studied and photographed with a Motic BA 310 petrographic microscope.

199

200 -----Please insert Plate 1 near here-----

201 -----Please insert Plate 2 near here-----

202

203 **4.2. Trace element concentration and strontium-isotope analysis**

204 Eleven oyster shells were sampled for SIS. Four oysters were obtained from the
205 Fredes section, all of them belonging to the Cantaperdius Formation (Fig. 4). In the
206 Herbers-Mas de Petxí section, six oyster samples were collected from the Artoles

207 Formation and one sample was gathered from the upper part of the Morella Formation
208 close to the top of the non-marine record (Fig. 3A–B).

209 Oyster shells were cleaned to remove superficial contamination and later polished
210 and screened for diagenetic changes. Visual inspection of the shells helped to prevent
211 the sampling of bioperforated parts, cements, and other alterations within the shell
212 structure. The externally non-altered parts of the shells were sampled with a hand-
213 operated microdrill equipped with a tungsten drill bit (0.3 to 0.5 mm in diameter) and
214 homogenised in an agate mortar mill. The resulting carbonate powder from each shell
215 was divided into two samples of ~100 mg. The first sample was employed for the
216 Inductively Coupled Plasma-Optical Emission Spectroscopy (ICP-OES) analysis of Ca,
217 Sr, Mg, Fe and Mn concentrations in order to perform diagenetic screening. This was
218 carried out at the Centres Científics i Tecnològics de la Universitat de Barcelona
219 (CCiTUB). The second sample was used for SIS, which was performed at the Unidad
220 de Geocronología, CAI de Ciencias de la Tierra y Arqueometría at the Universidad
221 Complutense de Madrid (Spain). Strontium (Sr) was separated from the sample by
222 standard ion-exchange resin methods. The Sr isotope ratios ($^{87}\text{Sr}/^{86}\text{Sr}$) were measured
223 on a TIMS-Phoenix[®] mass spectrometer. The analysis was corrected to avoid
224 interferences from ^{87}Rb , and the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio was normalised to the mean value of
225 0.1194. The analysed raw results were corrected using the standard NBS 987, which has
226 a value of 0.710249 ± 0.000012 (2 statistical uncertainty, $n = 7$).

227

228 **5. Stratigraphy and sedimentology**

229 A sedimentological analysis was performed in the Herbers-Mas de Petxí and
230 Fredes sections to determine the relationship between the presence or absence of
231 charophyte species and the depositional facies. Taphonomical features such as
232 fragmentation and abrasion, as well as the occurrence of different charophyte organs

233 together or even connected anatomically (i.e., fructifications and thalli), were
234 investigated to elucidate the degree of autochthony or allochthony of the charophyte
235 remains in the sedimentary record.

236

237 **5.1. The Herbers-Mas de Petxí section**

238 This section crops out to the south and south-east of the village of Herbers
239 (Castelló, Spain; Fig. 1C) and contains an 800 m-thick continuous Barremian
240 succession. The present study focuses on the lower 690 m, corresponding to the
241 Cantaperdius, Artoles, and Morella formations (Figs. 2 and 3A–B).

242 The Barremian succession is deposited above an irregular karstified surface
243 exhibiting vertical tubular structures that are interpreted as root marks marking the top
244 of the Hauterivian Herbers Formation (Fig. 2). The lowermost part of the Barremian
245 record (0–11 m), which corresponds to the base of the Cantaperdius Formation, consists
246 of variegated clays that change from a greyish colour at the base to a yellowish colour in
247 the middle and a reddish colour at the top. Similar deposits at the base of the Barremian
248 record in the Iberian Chain have been interpreted as laterite deposits (Combes 1969).
249 These clays contain charophyte remains (thalli and fructifications), ostracods and
250 molluscan fragments. Up to 0.5 m-thick packstones occur, interbedded with the clays.
251 The charophyte assemblage in the clays is mainly composed of utricles of well-
252 preserved *Atopochara trivolvris* var. *triquetra*, *Clavator harrisii* var. *harrisii*, *Ascidiella*
253 *stellata* var. *stellata* and *A. triquetra*, as well as gyrogonites of aff. *Mesochara harrisii*.
254 Charophyte thalli portions, *Munieria grambastii* Bystrický and *Favargerella aquavivae*
255 Martín-Closas et Salas, have been also observed, suggesting that the charophyte
256 assemblage is autochthonous. Utricles of *Hemiclavator adnatus* and *H. neimongolensis*
257 var. *posticecaptus* are rare and occur abraded. They are therefore interpreted as

258 allochthonous components. Above these clays, the section has been divided into eight
259 descriptive intervals, from A to H (see Fig. 3A-B).

260 **Interval A** (11–161.5 m) mainly consists of charophyte-rich massive dark-grey
261 limestones and marls that are stacked in parasequences. The marls are frequently absent
262 from the parasequences, but when they do occur, they consist of thin (<20 cm) layers
263 that contain abundant clavatoracean utricles associated with thalli and ostracods. The
264 marls are interbedded with limestones whose texture varies among mudstone,
265 wackestone and packstone and contain abundant clavatoracean utricles and thalli,
266 ostracods, and black pebbles (<1 mm across). These limestones often show colour
267 mottling. The top of the packstones is characterised by the presence of root marks.
268 Successions with these sedimentary features have been attributed to shallow carbonate
269 lakes laterally associated with palustrine environments (see, e.g., Gierlowski-Kordesch
270 2010, Alonso-Zarza and Wright 2010). Similar sedimentary settings have been
271 described by Platt (1989) and Meléndez et al. (2009) in other parts of the Lower
272 Cretaceous Iberian Chain.

273 The charophyte assemblages in this interval are mainly of *A. trivolvis* var.
274 *triquetra*, *Clavator harrisii* var. *dongjingensis*, var. *harrisii*, and var. *reyi*, *Ascidiella*
275 *stellata* var. *stellata*, and var. *lata*, *A. triquetra* and, rarely, *Globator maillardii* var.
276 *trochiliscoides*, *Hemiclavator adnatus*, *H. neimongolensis* var. *posticecaptus*, aff.
277 *Mesochara harrisii* and *Porochara maestratica*. Most samples contain well-preserved
278 fructifications that are associated with the charophyte thalli of *F. aquavivae*,
279 *Clavatoraxis* sp., *Charaxis* sp., and *M. grambastii*. Utricles of the genus *Ascidiella* are
280 locally found attached to *F. aquavivae* thalli portions while *C. harrisii* var. *harrisii*, *H.*
281 *adnatus* and *H. neimongolensis* var. *posticecaptus* are attached to *Clavatoraxis* sp.
282 phylloids. Taphonomic data show that these assemblages can be regarded as
283 autochthonous. Populations of *P. maestratica* are frequently small, but, locally, this

284 species can dominate charophyte assemblages. Porocharacean-rich autochthonous
285 assemblages from the Lower Cretaceous are interpreted as evidence of brackish water
286 conditions (e.g., Martín-Closas and Grambast-Fessard 1986, Schudack 1993, Climent-
287 Domènech et al. 2009).

288 **Interval B** (161.5–187 m) is formed of interbedded marls and limestones, with
289 the marl beds being more abundant and thicker than those in Interval A. The marl layers
290 are <50 cm thick and contain abundant charophyte thalli and fructifications (utricles and
291 gyrogonites), ostracods, gastropods and, rarely, small agglutinated benthic foraminifera.
292 Limestones are up to 1 m-thick and exhibit wackestone and packstone textures with a
293 palaeontological content similar to that observed in the limestones of Interval A. Root
294 marks at the top of the limestone beds also occur, suggesting deposition in very shallow
295 lake and palustrine environments (cf. Alonso-Zarza and Wright 2010). As in Interval A,
296 Interval B presents indications of lacustrine deposition with scarce palustrine
297 intercalations and a low exposition rate. However, the thicker marl layers in Interval B
298 compared to Interval A suggests that the freshwater alkaline lakes received higher
299 clastic input than those described for Interval A (e.g., Meléndez et al. 2009).

300 The charophyte assemblage in this interval is similar to that observed in the
301 interval A (Fig. 3A). The only differences are the first occurrences of *Echinochara*
302 *lazarii* and, locally, *Globator maillardii* var. *biutricularis*. Moreover, *G. maillardii* var.
303 *trochiliscoides* is more frequent and abundant here than in the underlying interval. The
304 last occurrences of *A. stellata* var. *stellata* and *Hemiclavator adnatus* are also recorded
305 in this interval. Most samples contain well-preserved fructifications that are associated
306 with thalli, suggesting autochthony. However, the gyrogonites of *P. maestrica* and the
307 benthic foraminifera are frequently broken and/or abraded, which indicates lateral
308 transport.

309

310 -----Please insert Fig. 3A near here-----

311

312 **Interval C** (187–276 m) is mainly composed of a succession of clavatoracean-
313 rich mudstone to packstones, resulting in a crest landscape. Occasionally, the limestones
314 are interbedded with <20 cm-thick marl beds. The palaeontological content of the
315 limestones and marls is similar to that of Interval A. They also show intraclasts and root
316 marks at the top, sedimentary features that indicate lakeshore environments (e.g.,
317 Gierlowski-Kordesch 2010; Alonso-Zarza and Wright 2010).

318 The charophyte assemblages in this interval are composed of *E. lazarii*, *A.*
319 *trivolis* var. *triquetra*, *C. harrisii* var. *harrisii*, and var. *reyi*, *Asciidiella stellata* var.
320 *lata*, *A. triquetra*, *H. neimongolensis* var. *posticecaptus* and *H. neimongolensis* var.
321 *neimongolensis* and gyrogonites of *P. maestratica* and aff. *M. harrisii*. They are mostly
322 formed of well-preserved fructifications associated with thalli, indicating that the
323 observed charophyte remains are autochthonous. The occurrence of porocharacean-
324 dominated limestones interbedded with clavatoracean-rich limestones is interpreted as
325 evidence of brackish water environments laterally associated with freshwater lakes,
326 similar to Interval A.

327 **Interval D** (276–366 m) is another interval with abundant marl and comprises the
328 uppermost part of the Cantaperdius Formation and the lowermost part of the Artoles
329 Formation. The lower part of the interval (276–348 m) is composed of a monotonous
330 succession of interbedded marls and packstones. While marls contain abundant
331 charophyte fructifications and thalli, ostracods, and gastropods, limestones contain
332 abundant charophyte thalli (mainly *M. grambastii*), few charophyte fructifications, and
333 large intraclasts (>1 cm in diameter). Root marks and ferruginous surfaces are common
334 at the top of the limestones. The facies slightly change in the upper part of the interval
335 (348–366 m). The marls of this upper part contain abundant, but poorly diverse

336 clavatoracean utricles, together with small agglutinated benthic foraminifera, and few
337 ostracods. These marls are interbedded with mudstone-wackestone limestones
338 containing a few charophyte utricles and thalli as well as ostracods. They are also
339 occasionally interbedded with oyster-bearing packstones. The lower part of the interval
340 is interpreted as deposited in a lacustrine setting. The root-marked limestones
341 correspond to lakeshore areas surrounded by a palustrine zone, similar to those
342 described by Meléndez et al. (2009) and Alonso-Zarza and Wright (2010) in other
343 Lower Cretaceous Iberian basins. Upwards, the succession shows a progressive
344 substitution of the freshwater lake facies by the brackish and oyster-bearing coastal
345 marine deposits of the Artoles Formation (Fig. 2), which mark the onset of the early
346 Barremian transgression in the basin (Bover-Arnal et al. 2016).

347 The charophyte assemblages of Interval D are mainly composed of *E lazarii*, *G.*
348 *maillardii* var. *trochiliscoides*, and var. *biutricularis*, *A. trivolvis* var. *triquetra*, *C.*
349 *harrisii* var. *dongjingensis* (last occurrence), var. *harrisii*, and var. *reyi*, *Clavator*
350 *calcitrapus* var. *jiangluoensis*, and var. *calcitrapus* (first occurrence), *Hemiclavator*
351 *neimongolensis* var. *neimongolensis*, and aff. *M. harrisii*. Occasionally, they also
352 include *Asciidiella stellata* var. *lata*, *A. triquetra*, *H. neimongolensis* var. *posticecaptus*
353 (last occurrence) and *P. maestratica*. Most samples show well-preserved utricles and
354 gyrogonites, occasionally attached to thalli. They are thus considered to be
355 autochthonous. The gyrogonites of *P. maestratica* show abrasion, indicating reworking
356 or lateral transport.

357 **Interval E** (366–450 m) represents the lower part of the Artoles Formation (Fig.
358 3B). It begins with 30 m of interbedded marls and wackestone limestones rich in well-
359 preserved gyrogonites of *P. maestratica*, small agglutinated benthic foraminifera, and
360 ostracods, indicating brackish water settings, as interpreted for Intervals A and C. The
361 marl layers can also contain scarce utricles of *E. lazarii*. These porocharacean-rich beds

362 are overlaid by 54 m of mudstone to packstones that contain agglutinated benthic
363 foraminifera, miliolids, oyster shells, gastropods, and rare porocharacean gyrogonites.
364 In these facies, porocharacean gyrogonites are slightly abraded, suggesting lateral
365 transport. These marine limestones are interpreted as shallow water facies that were
366 deposited in marginal coastal areas of a carbonate shelf (e.g., Tucker 1985).
367 Accordingly, Interval E shows an evolution of depositional environments from brackish
368 water settings dominated by porocharaceans at the base to shallow marine settings at the
369 top.

370 **Interval F** (450–490 m) belongs to the Artoles Formation at the base and to the
371 Morella Formation at the top (Fig. 3B). The lower 28 m (450–478 m) are composed of
372 >2 m-thick marls interbedded with 0.5–1 m-thick limestones. The palaeontological
373 assemblage found in the marls includes abundant charophyte thalli and clavatoracean
374 fructifications, ostracods, and molluscs. The limestones contain ostracods, gastropods,
375 bivalves, dasycladaleans, benthic foraminifera, and rare clavatoracean fructifications
376 and thalli. The top of the limestones is characterised by a ferruginous hardground
377 surface, locally encrusted by oysters. The upper 12 m (478–490 m) of the interval
378 shows a very distinct facies succession, characterised by repetitive interbedded grey and
379 red clays. These clays contain abundant and diverse charophytes associated with
380 ostracods, gastropods, and litioloid foraminifera. The lithofacies have strong similarities
381 with those described by Gámez et al. (2003) for the Morella Formation in the
382 depocentre of the Maestrat Basin (Salzedella Sub-basin; Fig. 1B). Consequently, these
383 clays are ascribed to the Morella Formation. The depositional setting of Interval F is
384 interpreted to have evolved from marginal coastal marine settings in the lower 28 m and
385 from brackish non-marine environments in the upper 12 m.

386 The charophyte assemblages are rich in *E. lazarii*. Less abundant charophytes
387 include *G. maillardii* var. *trochiliscoides*, and var. *biutricularis*, *A. trivolvis* var.

388 *triquetra*, *C. harrisii* var. *reyi*, *Asciadiella cruciata* (first occurrence), *H. neimongolensis*
389 var. *neimongolensis*, *Pseudoglobator paucibracteatus* (first occurrence), aff. *M.*
390 *harrisii*, and *P. maestratica*. Fertile whorls of *E. lazarii* are frequently preserved, and
391 two utricles were found anatomically attached the corresponding thalli, i.e., *Charaxis*
392 *spicatus* Martín Closas et Diéguez, suggesting autochthony. The other fructifications of
393 the assemblage (*G. maillardii* var. *trochiliscoides* and var. *biutricularis*, *A. trivolvus* var.
394 *triquetra*, *C. harrisii* var. *harrisii* and var. *reyi*, *A. cruciata*, *H. neimongolensis* var.
395 *neimongolensis*, *P. paucibracteatus*, aff. *M. harrisii* and *P. maestratica*) are well-
396 preserved or slightly eroded, which suggests parautochthony.

397

398 -----Please insert Fig. 3B near here-----

399

400 **Interval G** (490–611 m) corresponds to the upper part of the Artoles Formation in
401 the Herbers-Mas de Petxí section (Fig. 3B). It mainly consists of marls alternating with
402 cross-bedded packstone-grainstone limestones. The marls frequently contain bivalve
403 moulds. The limestones are lenticular and show a lateral thinning from 2 m in the
404 central parts to 0.3 m at the edges of the bed. The bioclastic components of the
405 limestones mainly correspond to oysters, gastropods, echinoids, dasycladales, and
406 benthic foraminifera. At the base, the limestone beds contain abundant mud pebbles.
407 The occurrence of cross-bedding, lateral thinning of the beds, and the presence of
408 intraclasts at the base, indicates that these limestones correspond to channel-fill deposits
409 formed in shallow marine settings (e.g., Tucker 1985, Bover-Arnal and Strasser 2013).
410 Above the channelised beds, a 7 m-thick laminated mudstone limestone with thin
411 calcified filaments occurs. The laminae of this mudstone are a millimetre-thick and
412 contain benthic foraminifera and very small mollusc bioclasts. This deposit represents a
413 microbial algal mat formed in intertidal to shallow subtidal areas, resembling the one

414 reported by Tucker (1985) and Bover-Arnal and Strasser (2013). Thus, the interval is
415 attributed to a deposition in a tidal flat.

416 The charophyte assemblages of this interval are mainly composed of well-
417 preserved utricles of *Echinochara lazarii*, which are considered autochthonous. Small
418 populations of *G. maillardii* var. *biutricularis* and *A. cruciata* are well-preserved to
419 slightly eroded, suggesting parautochthony.

420 **Interval H** (611–680 m) is ascribed to the Morella Formation, being the second
421 interval attributed to this formation in Herbers-Mas de Petxí (Fig. 3B). It starts with a 1
422 m-thick red clay interval followed by a 1.5 m-thick charophyte-rich limestone. The
423 following 37 m are characterised by up to 5 m-thick layers of variegated clays (grey,
424 red, ochre, and purple) that contain abundant charophyte remains (thalli and
425 fructifications), ostracods, and agglutinated benthic foraminifera. Red and purple clays
426 show mottled areas and contain abundant root marks. Thin (3–20 cm-thick)
427 wackestone-packstones occur, interbedded with the clays. These limestones are rich in
428 charophyte utricles and thalli, found sometimes anatomically connected, as well as
429 ostracods and molluscs. The uppermost 30.5 m of the interval (649.5–680 m) are
430 composed of a succession of grey and red clays interbedded with packstones that are
431 rich in oysters and ostracods and frequently exhibit bioturbated tops. The microfossil
432 content of the clays resembles that of the basal part of the interval, mainly containing
433 charophyte fructifications and thalli, ostracods, and agglutinated benthic foraminifera.
434 The top of this stratigraphic interval is marked by a 2 m-thick, cross-bedded and
435 bioturbated packstone limestone rich in bivalve fragments and ostracods, similar to the
436 channel-fill deposits observed in the underlying interval.

437 Similar clay-dominated deposits occur in the type locality of the Morella
438 Formation, where they are associated with conglomerates and sands, thus being
439 interpreted as deposited in a mudflat environment (Gàmez et al. 2003). In the studied

440 section, lacustrine limestones occur interbedded with clays and sandstone, unlike in the
441 type locality. These limestones may correspond to temporary lakes or ponds that were
442 formed in poorly-drained areas of mudflats, such as those reported by Bádenas et al.
443 (2018) in the Tithonian–Berriasian record from the Galve Sub-basin (Fig. 1B). In the
444 upper part of the interval (649.5–680 m), the clay deposits change upwards into
445 channel-fill ostracod-rich limestones that mark the beginning of a long-term late
446 Barremian–early Aptian transgression (Bover-Arnal et al. 2016). This interval
447 represents the last non-marine deposits in the studied section.

448 The charophyte assemblage is very similar throughout the interval and strongly
449 resembles that observed in Interval F. In this regard, *Atopochara trivolis* var. *trivolis*,
450 *Clavator grovesii* var. *jiuquanensis*, and *C. harrisii* var. *harrisii* appear in this interval,
451 but are absent in Interval F. *Porochara maestatica* is found in Interval F but is absent
452 in interval H. *E. lazarii*, *A. trivolis* var. *triquetra* and var. *trivolis*, *C. harrisii* var. *reyi*
453 and var. *harrisii* are abundant, well-preserved and occasionally attached to the thalli
454 portions, suggesting autochthony. The utricles of *G. maillardii* var. *trochiliscoides* and
455 var. *biutricularis*, *Clavator grovesii* var. *jiuquanensis*, *A. cruciata*, *H. neimongolensis*
456 var. *neimongolensis*, *P. paucibracteatus*, and gyrogonites of aff. *M. harrisii* are less
457 abundant and occasionally slightly abraded, indicating short lateral transport and
458 parautochthony. Benthic foraminifera are abundant and well-preserved, indicating a
459 marine influence, which is commonly described for mudflat settings (c.f. Bádenas et al.
460 2018).

461

462 **5.2. The Fredes section**

463 The Fredes section is exposed between kms 8 and 9 of the road CV-106 (Fig. 1D)
464 and consists of a ~100 m-thick continuous Barremian succession that belongs entirely to
465 the Cantaperdius Formation. It lies on the Herbers Formation, Hauterivian in age (e.g.,

466 Salas et al. 2001). The basal laterite of the Cantaperdius Formation consists of ~2.5 m of
467 yellowish and red clays that are topped by a mudstone limestone with root marks. The
468 charophyte assemblage in the laterite is mainly composed of *A. trivolvis* var. *triquetra*,
469 *A. stellata* var. *stellata*, *H. neimongolensis* var. *posticecaptus*, and gyrogonites of *P.*
470 *maestratica* and aff. *M. harrisii*. Thalli portions belonging to *Clavatoraxis* sp.,
471 *Favargerella aquavivae* and *Munieria grambastii* are rare, suggesting a
472 parautochthonous assemblage. Above the laterite, the section is divided into five
473 descriptive intervals A–E (Fig. 4). The laterite and the lower 10 m of the section are
474 repeated as the section is faulted.

475 **Interval A** (2.5–10.25 m and 13–26 m) is characterised by the occurrence of
476 lenticular limestone beds interbedded with marls. The marls form up to 1 m-thick beds
477 that are rich in charophyte thalli and fructifications, ostracods, molluscs and, frequently,
478 agglutinated benthic foraminifera, dasycladaleans, and vertebrate teeth. The limestones
479 are up to 3 m-thick (most commonly 1.5 m-thick). Their base is erosive and
480 characterised by lag deposits with a packstone texture containing molluscs, ostracods,
481 intraclasts, and rare charophyte thalli. Above the lag, the limestone is a mollusc-rich
482 wackestone-mudstone, forming a thinning-upwards sequence. Root marks as well as
483 nodular and intraclastic fabrics are observed at the top of the limestones.

484 The marls are interpreted as deposited in shallow lakes. The co-occurrence of
485 freshwater and brackish water organisms suggests that these lakes were probably
486 established in a coastal area that experienced alternating periods of freshwater and
487 marine influences. The overlying lenticular limestone beds are very similar to other
488 carbonate channel-fill deposits associated with lacustrine and palustrine areas (e.g., Platt
489 1989, Alonso-Zarza and Calvo 2000). The occurrence of intraclasts and the similarity of
490 the fossil contents of the limestones and the underlying marl intervals suggest the
491 reworking of the previously deposited shallow lake deposits during the sedimentation of

492 the channel-fill deposits. Nodular textures and root marks at the top of these lenticular
493 beds indicate the abandonment of the channel and the establishment of palustrine
494 conditions (see, e.g., Alonso-Zarza and Wright 2010).

495 The charophyte assemblage found in the marls is mainly composed of the utricles
496 of *A. trivolis* var. *triquetra*, *A. stellata* var. *stellata* and var. *lata* (first occurrence), *A.*
497 *triquetra* and *H. neimongolensis* var. *posticecaptus*. These utricles are well-preserved
498 and frequently occur associated with or attached to thalli (*Clavatoraxis* sp., *F.*
499 *aquavivae* and *M. grambastii*), suggesting autochthony. On the other hand, *G.*
500 *maillardii* var. *trochiliscoides*, *C. harrisii* var. *dongjingensis*, *C. harrisii* var. *harrisii*,
501 aff. *M. harrisii* and *P. maestratica* are rare and frequently abraded, and found associated
502 with well-preserved dasycladalean and benthic foraminifera. This latter charophyte
503 assemblage is considered parautochthonous in the sample.

504 **Interval B** (26–40.75 m) is formed of two different parts. The lower part (26–36
505 m) is characterised by decimetre-thick limestone beds, frequently showing vertical root
506 marks and nodular fabrics at the top, which are interbedded with thinner layers of marl,
507 all of them rich in charophyte thalli and fructifications as well as ostracods. The upper
508 part of the interval (35–40.75 m) starts with a thin marl bed containing abundant
509 charophyte remains (utricles, gyrogonites and thalli) together with abundant
510 agglutinated benthic foraminifera, molluscs and echinoid fragments. Above the marl
511 layer, the interval consists of repeating limestone parasequences composed of a basal
512 massive up to 2 m-thick wackestone that contains porocharacean gyrogonites, benthic
513 foraminifera, echinoid fragments, and rare clavatoracean remains, followed by a 0.2 m-
514 thick nodular limestone.

515 The lower part of the interval (26–35 m) is interpreted as a deposition in
516 freshwater shallow lakes that were later subaerially-exposed and, thus, the original rock
517 texture was modified by the establishment of palustrine conditions (see, e.g., Freytet

518 and Plaziat 1982, Alonso-Zarza and Wright 2010). The upper interval (35–40.75 m) was
519 probably deposited in coastal environments, with changing salinity and frequent
520 desiccation and emersion, as demonstrated by the presence of nodular limestones (see
521 similar examples in Alonso-Zarza and Wright 2010).

522 The charophyte assemblage identified in the marls of this interval resembles that
523 described in the previous interval, but with a slightly different preservation. The utricles
524 of *G. maillardii* var. *trochiliscoides* and, locally, *G. maillardii* var. *biutricularis* (first
525 occurrence) and *A. trivolvis* var. *triquetra* are abundant and well-preserved (indicating
526 autochthony), while those of *C. harrisii* var. *harrisii*, *A. stellata* var. *stellata* and var.
527 *lata*, *A. triquetra*, *H. neimongolensis* var. *posticecaptus*, aff. *M. harrisii* and *P.*
528 *maestratica* are scarce and can be abraded. The benthic foraminifera associated with the
529 charophytes are also abundant and well-preserved, suggesting a process of time
530 averaging between the deposition of the two different assemblages (freshwater and the
531 brackish to marine water, respectively).

532

533 -----Please insert Fig. 4 near here-----

534

535 **Interval C** (40.75–71.5 m) is characterised by marl beds interbedded with
536 limestones. The marls are up to 2.5 m-thick and contain charophyte thalli and
537 fructifications (utricles and gyrogonites), ostracods, mollusc and echinoid fragments,
538 agglutinated benthic foraminifera, dasycladales and vertebrate teeth. The limestones are
539 0.25 to 1.5 m-thick and frequently display rootlet marks or nodular fabrics at the top.
540 There are three types of deposits: (1) massive clavatoracean-rich limestones containing
541 abundant clavatoracean utricles and thalli, ostracods, and molluscs, (2) massive
542 limestones rich in benthic foraminifera and fragments of molluscs, dasycladales, and
543 echinoids, and (3) lenticular cross-bedded bioclastic limestones with molluscs,

544 dasycladales, and benthic foraminifera that exhibit a basal lag deposit and become
545 more fine upwards into a wackestone containing the same fossil content.

546 This interval is interpreted as coastal-marginal settings with alternating freshwater
547 and brackish to marine water influences. Root marks and nodular fabrics observed at the
548 top of some of the limestone beds indicate palustrine settings with subaerial exposition
549 (e.g., Freytet and Plaziat 1982, Alonso-Zarza and Wright 2010). The lenticular cross-
550 bedded bioclastic limestones observed at the top of the interval correspond to channel-
551 fill deposits, probably formed in a coastal marine-influenced area.

552 The charophyte assemblages in this interval are mainly composed of well-
553 preserved utricles of *G. maillardii* var. *trochiliscoides* (rarely *G. maillardii* var.
554 *biutricularis*) and *A. trivolvis* var. *triquetra*. Occasionally, *E. lazarii* (first occurrence),
555 *C. harrisii* var. *dongjingensis*, var. *harrisii*, and var. *reyi* (first occurrence), *A. stellata*
556 var. *stellata* (last occurrence), and var. *lata*, *A. triquetra* and *H. neimongolensis* var.
557 *posticecaptus* (last occurrence) and var. *neimongolensis* (first occurrence), aff. *M.*
558 *harrisii*, and *P. maestatica* do also occur. As in the underlying intervals A and B,
559 samples with a higher abundance and better preservation of charophyte remains contain
560 scarce, abraded and/or fragmented remains of marine organisms, while those with a
561 higher abundance of marine organisms contain scarce and frequently abraded
562 charophyte remains.

563 **Interval D** (71.5–88 m) is composed of thick limestone beds that are
564 characterised by the frequent presence of oncoids and intraclasts. The marl layers
565 interbedded with these limestones are very thin and contain charophyte thalli and
566 fructifications, ostracods, molluscs and, occasionally, vertebrate teeth, dasycladales, and
567 miliolids. The base of the interval (71.5–82 m) consists of two 5 m-thick parasequences,
568 the bottom of which displays two up to 1 m-thick marl beds that are separated by a 0.5
569 m-thick charophyte-rich packstone limestone. Above this, each parasequence continues

570 with a 3 m-thick massive or laminated wackestone limestone containing large (~1 cm in
571 diameter) black pebbles and oncoids. The upper part of Interval D (82–88 m) is
572 distinguished by the occurrence of limestone beds with a massive fabric at the base that
573 becomes nodular to brecciated at the top. These limestones are interbedded with thin
574 layers of marl.

575 The whole interval is interpreted as a shallow lacustrine to palustrine succession.
576 Black pebbles suggest more hydrodynamic lakeshore areas (e.g., Gierlowski-Kordesch
577 2010). The interbedding of nodular and brecciated limestones indicates palustrine facies
578 (e.g., Alonso-Zarza and Wright 2010), while the massive limestones correspond to well-
579 oxygenated lacustrine deposits (e.g., Gierlowski-Kordesch 2010). The absence or
580 scarcity of remains from marine organisms indicates a deposition in freshwater settings.

581 The charophyte assemblage in this interval is mainly formed of well-preserved *A.*
582 *trivolis* var. *triquetra* and, occasionally, superficially eroded specimens of *G.*
583 *maillardii* var. *trochiliscoides* and var. *biutricularis*, *A. stellata* var. *lata*, *A. triquetra*, *H.*
584 *neimongolensis* var. *neimongolensis*, aff. *M. harrisii* and *P. maestrica*. *E. lazarii* is
585 rare, but showing complete fertile whorls. In the uppermost part of the interval (82–88
586 m), charophyte biodiversity increases and the assemblages are composed of well-
587 preserved fructifications of the aforementioned taxa together with those of *Clavator*
588 *grovesii* var. *gautieri* and *C. harrisii* var. *reyi* that are associated with thalli (*F.*
589 *aquavivae*, *Clavatoraxis* sp., and *Charaxis* aff. *spicatus*), sometimes in anatomical
590 connection, indicating an autochthonous assemblage.

591

592 -----Please insert Fig. 5 near here-----

593

594 **Interval E** (88–98 m) is dominated by massive (locally nodular) clavatoracean-
595 rich marl beds that are up to 1.7 m-thick and contain ostracods, and molluscs. These are

596 interbedded with up to 1 m-thick limestones. Based on textures and fossils, two
597 microfacies can be distinguished: (1) oyster-rich grainstones that also contain
598 gastropods and benthic foraminifera, and (2) wackestone limestones rich in
599 porocharacean gyrogonites that also contain less-abundant molluscs and benthic
600 foraminifera. The whole interval is interpreted as coastal shallow lakes, laterally-
601 associated with brackish water and marine environments.

602 This interval contains richer charophyte assemblages than those observed in the
603 underlying interval, including *E. lazarii*, *G. maillardii* var. *trochiliscoides*, and var.
604 *biutricularis*, *A. trivolvis* var. *triquetra*, *C. grovesii* var. *gauteri*, *C. harrisii* var.
605 *dongjingensis* (last occurrence), var. *harrisii*, and var. *reyi*, *Clavator calcitrapus* var.
606 *jiangluoensis*, and var. *calcitrapus* (first occurrence), *A. stellata* var. *lata*, *A. triquetra*,
607 *H. neimongolensis* var. *neimongolensis*, and rarely also *P. maestratica* and aff. *M.*
608 *harrisii*. The utricles and gyrogonites are generally well-preserved and associated with
609 charophyte thalli (*Charaxis* sp., *Clavatoraxis* sp., *F. aquavivae*, and *M. grambastii*),
610 suggesting autochthony of the charophyte assemblage.

611

612 **6. Strontium-Isotope Stratigraphy (SIS)**

613 **6.1. Preservation of the original $^{87}\text{Sr}/^{86}\text{Sr}$ signature**

614 Evaluation of the preservation state of low-Mg calcite shells is a primary
615 requirement in SIS. Diagenetic processes during burial may modify the original
616 $^{87}\text{Sr}/^{86}\text{Sr}$ ratio, resulting in an erroneous derivation of the age. The analysis of major and
617 trace elements is an effective tool to evaluate any changes in biogenic samples (e.g.,
618 Steuber et al. 2005, Bodin et al. 2009, Huck et al. 2011, Frijia et al. 2015, Bover-Arnal
619 et al. 2016, Caus et al, 2016, González-León et al. 2017). Diagenetic alterations in
620 biogenic samples commonly result in a decrease in Sr concentration and an increase in
621 Fe and Mn concentrations as well as in the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio (Brand and Veizer 1980,

622 Wenzel 2000). However, these trends were not observed in our results, which are
623 summarised in Table 2. Except for sample OyFr1, which is clearly altered due to
624 diagenesis, the Sr concentrations are >700 ppm (Table 2). A Sr concentration > 700
625 ppm is usually considered a minimum value for discriminating between non-
626 diagenetically-altered samples and diagenetically-altered samples (e.g., Boix et al.,
627 2011; Frijia et al., 2015). Moreover, in most samples, the Mn and Fe concentrations are
628 above the threshold values (50 ppm and 250 ppm, respectively) that discern between
629 diagenetically-altered and non-diagenetically-altered samples (e.g., Steuber 1999,
630 2001). However, high Fe and Mn concentrations have also been linked to sedimentary
631 processes. Schneider et al. (2009) indicated that in marginal marine conditions, Fe and
632 Mn concentrations can be affected by freshwater influx and suggested cut-off values of
633 Mn <250 ppm and Fe <700 ppm for oysters found in such settings. On the other hand,
634 low Mn and Fe concentrations can also occur in diagenetic calcite (Steuber et al. 2005,
635 Boix et al. 2011, Frijia et al. 2015, Bover-Arnal et al. 2016, Caus et al. 2016).
636 Therefore, low Mn and Fe concentrations and high Sr concentrations have to be used
637 cautiously as indicators of non-diagenetic overprint of biogenic low-Mg calcite.

638 In our dataset, 6 out of the 10 samples (OyFr2, OyFr21c, OyH3, OyH4, OyH6,
639 and OyH7; Table 2) have Mn and Fe concentrations that are below the threshold values
640 (Mn < 250 ppm and Fe < 700 ppm) distinguishing between diagenetically-altered and
641 non-diagenetically-altered oyster shells from marginal marine environments (e.g.,
642 Schneider et al., 2009; Horikx et al., 2014). Following Brasier et al. (1994), Denison et
643 al. (1994) and Rosales et al. (2001), we used the Mn/Sr and Fe/Sr ratios to discern
644 between diagenetically-altered and non-diagenetically-modified samples (Table 2).
645 Ratios of Mn/Sr <0.5 and Fe/Sr <0.3 were proposed by Brasier et al. (1994) to
646 distinguish between altered and non-altered carbonates. Based on this criterion, only

647 three samples, OyFr21c, OyH4 and OyH6 (Table 2), preserved non-altered $^{87}\text{Sr}/^{86}\text{Sr}$
648 values and were finally used to derive the numerical ages.

649 The discarded samples OyH3 and OyH7 show Sr-isotope ratios of 0.707515 and
650 0.707504, respectively, which are not in agreement with the marine $^{87}\text{Sr}/^{86}\text{Sr}$ ratios
651 published for the Barremian Stage. According to McArthur et al. (2012), the Barremian
652 Sr-isotope values range between 0.707471 and 0.707432, whereas McArthur et al.
653 (2020) give a range between 0.707470 and 0.707426. The oyster shells OyFr2, OyH3
654 and OyH7 discarded were collected from beds that contain abundant and well-preserved
655 charophytes (Figs. 3B and 4). Therefore, the isotopic signal of these samples was
656 probably modified by freshwater influence (see e.g., Benito et al. 2020; Table 2).

657

658 **6.2. Strontium ratios and the derived numerical ages**

659 Non-diagenetically-altered samples used for SIS were collected from the
660 Cantaperdius Formation (sample OyFr21c) and the Artoles Formation (samples OyH4
661 and OyH6) (Figs. 3A-B and 4; Table 2). The $^{87}\text{Sr}/^{86}\text{Sr}$ ratios obtained from the low-Mg
662 calcite oyster shells from these units vary from 0.707481 ± 0.000012 to $0.707489 \pm$
663 0.000012 (Table 2). Taking into account the stratigraphic context, these values were
664 converted into numerical ages using the ‘LOWESS 5 fit 26 03 13’ look-up table of
665 McArthur, which is linked to the Geologic Time Scale 2012 (GTS2012) of Gradstein et
666 al. (2012), and the ‘LOESS 6 16 03 2020’ look-up table of McArthur (J. McArthur,
667 personal communication, 2021), which is linked to the Geologic Time Scale 2020
668 (GTS2020) of Gradstein et al. (2020). In both Geologic Time Scales, the whole-time
669 range of the samples is latest Hauterivian–late Barremian (Table 2). The reason why
670 these $^{87}\text{Sr}/^{86}\text{Sr}$ values translate into such a wide time span is due to the slow increase in
671 the $^{87}\text{Sr}/^{86}\text{Sr}$ ratios between the early Barremian and the early late Barremian (see, e.g.,
672 Jones and Jenkins 2001, McArthur et al. 2001, 2012, 2020, Mutterlose et al. 2014, Wan

673 et al. 2019). However, the data available on charophyte biostratigraphy at the base of
674 the studied sections constrains the age of these samples to the Barremian (e.g., Martín-
675 Closas and Salas 1994, Martín-Closas 2000).

676 According to the numerical ages derived from the ‘LOWESS 5 fit 26 03 13’ look-
677 up table of McArthur, which is linked to the GTS2012, the $^{87}\text{Sr}/^{86}\text{Sr}$ ratios indicate
678 preferred ages of between 129.80 and 129.00 Ma, dating the analysed specimens to the
679 early Barremian–early late Barremian. Considering the statistical uncertainty (2 s.e.),
680 the total age range for the samples is 130.95–128.25 Ma (latest Hauterivian–late
681 Barremian; Ogg and Hinnov, 2012).

682 The oldest low-Mg calcite sample was obtained from the Cantaperdius Formation
683 in the Fredes section (sample OyFr21c; Fig. 4). The $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of this sample is
684 0.707481 ± 0.000012 , translating into a preferred numerical age of 129.80 Ma (+1.15/-
685 0.60). This numerical age corresponds to the late early Barremian (Ogg and Hinnov,
686 2012). The two other analysed samples were obtained from the Herbers-Mas de Petxí
687 section (Fig. 3A–B). Sample OyH4 was obtained from the lower part of the Artoles
688 Formation and its $^{87}\text{Sr}/^{86}\text{Sr}$ ratio is 0.707482 ± 0.000012 , which translates into a
689 preferred age of 129.70 Ma (+1.20/-0.60), i.e., early Barremian (Ogg and Hinnov,
690 2012). The youngest low-Mg calcite shell sample was OyH6, which was obtained from
691 the topmost part of the Artoles Formation, specifically, 1.5 m below the second interval
692 of the Morella Formation in the Herbers-Mas de Petxí section (Fig. 3B). The $^{87}\text{Sr}/^{86}\text{Sr}$
693 value for this sample is 0.707489 ± 0.000012 , which translates into a preferred age of
694 129.00 Ma (+0.80/-0.75), corresponding to the early late Barremian (Ogg and Hinnov,
695 2012).

696 On the other hand, utilizing the ‘LOESS 6 16 03 2020’ look-up table of
697 McArthur, which is associated to the GTS2020, the preferred numerical ages fall within
698 the early Barremian and range between 126.10 and 125.05 Ma (Table 2). Taking into

699 account the statistical uncertainty, however, the total time span for the sample is
700 126.65–124.20 Ma (latest Hauterivian–early late Barremian according to Gale et al.
701 2020). However, this recent numerical calibration shows inconsistencies. For example,
702 according to the ‘LOESS 6 16 03 2020’, the preferred numerical age derived for sample
703 OyH6 is 125.05 Ma (Table 2) and falls within the early early Barremian. Sample OyH6
704 is 24 m below the first appearance of *Clavator grovesii* var. *jiuquanensis* (Fig. 3B),
705 which has been correlated with the *Toxanclyoceas vandenheckii* ammonoid biozone
706 (late Barremian) in the Subalpine Chains (Martín-Closas et al. 2009). According to Gale
707 et al. (2020), the base and top of the *Toxanclyoceas vandenheckii* Zone is dated to
708 124.4 and 123 Ma, respectively. This would imply that the 24 m of stratigraphic
709 succession found between sample OyH6 and the the first occurrence of *Clavator*
710 *grovesii* var. *jiuquanensis* (Fig. 3B) would record 0.65 My. Such a significant
711 sedimentary gap or slow rate of sedimentation seems unlikely given the overall
712 expansion and large thickness of the synrift succession studied (Fig. 3A-B). In
713 consequence, the biozonations presented herein follow the GTS2012, which provides a
714 more consistent chrono-biostratigraphic framework (Fig. 6), and is in agreement with
715 previous correlations between charophyte assemblages and ammonoid biostratigraphy
716 (Martín-Closas et al. 2009).

717

718 -----Please insert Table 2 near here-----

719

720 **7. Barremian-early Aptian charophyte biozonation**

721 The new data obtained from the two Barremian sections studied enabled us to
722 refine the Barremian-early Aptian European charophyte biozonation and extend its use
723 to most of the Cretaceous Tethyan Archipelago (mainly present-day Europe and North
724 Africa). Moreover, the new data led us to propose a new Barremian-early Aptian

725 Eurasian charophyte biozonation, whose index species were widely distributed from
726 Europe to China. The two biozonations are directly correlated to one another in Figures
727 3A–B, 4 and 6.

728

729 **7.1. The Barremian–early Aptian European charophyte biozonation**

730 The first proposal of a Barremian-early Aptian European charophyte biozonation
731 was from Grambast (1974) and was later modified by Martín-Closas and Salas (1994),
732 Riveline et al. (1996), and finally by Martín-Closas et al. (2009). The current
733 biozonation (after the revision of Martín-Closas et al., 2009) is composed of two partial
734 range biozones that are characterised at their bases by the FAD of *Atopochara trivolvis*
735 var. *triquetra* (early Barremian) and *Asciadiella cruciata* and *Pseudoglobator*
736 *paucibracteatus* (late Barremian-early Aptian; Fig. 6), respectively. Herein, we propose
737 to modify this biozonation by only using species that are known to have been endemic
738 in the Cretaceous Tethyan Archipelago. Following this criterion, *Globator maillardii*
739 var. *trochiliscoides* is proposed here as the index species of the early Barremian
740 charophyte biozone instead of *A. trivolvis* var. *triquetra*. This new index species was
741 extensively distributed and appears to have been endemic in Europe and most of the
742 Cretaceous Tethyan Archipelago (Martín-Closas, 2000; Martín-Closas and Wang 2010;
743 Pérez-Cano et al., 2020; Sanjuan et al. 2021), while *A. trivolvis* var. *triquetra*, which
744 had a cosmopolitan distribution during the Barremian (Martín-Closas and Wang, 2008),
745 is reserved for the Eurasian biozonation (see below). By contrast, the late Barremian–
746 early Aptian *Asciadiella cruciata*-*Pseudoglobator paucibracteatus* biozone is kept
747 unchanged in the new proposal (Fig. 6), since these index species are, so far, unique to
748 the Cretaceous Tethyan Archipelago.

749

750 ***Globator maillardii* var. *trochiliscoides* biozone**

751 **Definition.** Partial range biozone defining the interval between the FAD of
752 *Globator maillardii* var. *trochiliscoides* and the FAD of *Ascidiella cruciata* and
753 *Pseudoglobator paucibracteatus* (Figs. 3A–B and 6).

754 **Species assemblage:** *Echinochara lazarii*, *Globator maillardii* var. *trochiliscoides*
755 (dominant over *G. maillardii* var. *biutricularis*), *G. maillardii* var. *biutricularis*,
756 *Atopochara trivolvis* var. *triquetra*, *Clavator grovesii* var. *gautieri*, *C. harrisii* var.
757 *dongjingensis*, *C. harrisii* var. *harrisii* (dominant over var. *dongjingensis* and var. *reyi*),
758 *C. harrisii* var. *reyi*, *C. calcitrapus* var. *jiangluoensis*, *C. calcitrapus* var. *calcitrapus*,
759 *Ascidiella stellata* var. *stellata*, *A. stellata* var. *lata* (dominant over var. *stellata*), *A.*
760 *triquetra*, *A. iberica* var. *iberica*, *Hemiclavator adnatus*, *H. neimongolensis* var.
761 *posticecaptus*, *H. neimongolensis* var. *neimongolensis*, and *Pseudoglobator fourcadei*.

762 **Remarks.** A biozone based on *G. maillardii* var. *trochiliscoides* was previously
763 proposed by Mojon (1996) to characterise the late Barremian–early Aptian. The same
764 author proposed the *G. maillardii* var. *mutabilis* biozone for the lower Barremian.
765 However, the populations of *G. maillardii* observed in the oldest assemblages studied
766 herein (in the lower part of the Cantaperdius Formation) do not show the basal utricle
767 features characteristic of *G. maillardii* var. *mutabilis* (cf. Martín-Closas 2000), fully
768 belonging to var. *trochiliscoides* instead. This criterion of homogeneous populations of
769 *G. maillardii* var. *trochiliscoides* was used to establish the base of the *G. maillardii* var.
770 *trochiliscoides* biozone. However, some utricles (<10%) of *G. maillardii* var.
771 *biutricularis* may occur in particular *G. maillardii* var. *trochiliscoides* populations of
772 this biozone, while *G. maillardii* var. *biutricularis* can be more frequent than *G.*
773 *maillardii* var. *trochiliscoides* or even dominant in the overlying *Ascidiella cruciata*-
774 *Pseudoglobator paucibracteatus* biozone, where it can form homogeneous populations
775 (e.g., Vicente and Martín-Closas 2013).

776 The *C. harrisii* populations in the *G. maillardii* var. *trochiliscoides* biozone are
777 dominated by *C. harrisii* var. *harrisii*, which is the typical variety in this biozone and
778 frequently forms homogeneous populations (Martín-Closas 2000 and references
779 therein). However, some utricles of *C. harrisii* var. *dongjingensis* and *C. harrisii* var.
780 *reyi* are repeatedly found in the studied samples to be in association with *C. harrisii* var.
781 *harrisii*. *C. harrisii* var. *dongjingensis* was typical and dominant between the late
782 Berriasian and late Hauterivian (Martín-Closas 2000). *C. harrisii* var. *reyi* occurs for the
783 first time in this biozone inside populations dominated by *C. harrisii* var. *harrisii*.
784 However, *C. harrisii* var. *reyi* is typical and dominant in the overlying Cruciatata-
785 Paucibracteatus biozone, where it forms homogeneous populations (e.g., Vicente and
786 Martín-Closas 2013).

787 *C. calcitrapus* var. *jiangluoensis* occurs in the lower part of the *G. maillardii* var.
788 *trochiliscoides* biozone, while *C. calcitrapus* s.s. occurs in the upper part of the biozone.
789 Therefore, the gradualistic evolution of *C. calcitrapus* described by Pérez-Cano et al.
790 (2020) allows more precise dating throughout this biozone.

791 Two more species are also characteristic of this biozone, although they have not
792 been identified in the stratigraphic sections studied here. These are *Asciadiella iberica*
793 var. *iberica* (Grambast) Martín-Closas ex Schudack, which occurs in association with *A.*
794 *trivolis* var. *triquetra* in several localities of the Iberian Chain in Spain and in the
795 Wealden Basin in England (Martín-Closas 2000 and Feist et al. 1995, respectively), and
796 *Pseudoglobator fourcadei* Grambast, which has been exclusively described in the
797 Prebaetic Chain (south-eastern Spain), where it occurs in association with *A. trivolis*
798 var. *triquetra* and *H. adnatus* (Martín-Closas 2000).

799 **Biostratigraphic correlations.** In the Iberian Chain, *G. maillardii* var.
800 *trochiliscoides* has been correlated with the orbitolinid foraminifer *Palaeodictyoconus*
801 *cuvillieri* (Combes et al., 1966). In the Subalpine Chains, *G. maillardii* var.

802 *trochiliscoides* has been correlated with the orbitolinid assemblage composed of
803 *Valserina broennimanni*, *Eopalorbitolina charollaisi*, *Orbitolinopsis debelmasi*,
804 *Cribellopsis elongata* and *Paracoskinolina hispanica*, corresponding to the *Nicklesia*
805 *nicklesi* ammonite Zone (Martín-Closas et al. 2009).

806 **Calibration based on SIS.** No calibration is available for the base of the biozone,
807 while its top coincides with the base of the next biozone, which is calibrated as
808 explained below.

809 **Age.** Early Barremian.

810

811 **Asciidiella cruciata-Pseudoglobator paucibracteatus biozone**

812 **Definition.** Time interval defined between the FAD of *Asciidiella cruciata* and
813 *Pseudoglobator paucibracteatus*, and the FAD of *Clavator grovesii* var. *lusitanicus*.

814 **Species assemblage.** *Echinochara lazarii*, *Globator mallardi* var. *trochiliscoides*,
815 *G. maillardii* var. *biutricularis* (dominant over var. *trochiliscoides*), *Atopochara*
816 *trivolvii* var. *triquetra* (dominant variety upon var. *trivolvii*), *Atopochara trivolvii* var.
817 *trivolvii*, *Clavator grovesii* var. *gautieri*, *C. grovesii* var. *jiuquanensis*, *C. harrisii* var.
818 *harrisii*, *C. harrisii* var. *reyi* (dominant over var. *harrisii*), *Hemiclavator*
819 *neimongolensis* var. *neimongolensis*, *Asciidiella cruciata*, *A. iberica* var. *inflata* and
820 *Pseudoglobator paucibracteatus*.

821 **Remarks.** Riveline et al. (1996) defined this biozone as a partial range biozone
822 described between the FAD of *A. cruciata* and the FAD of *C. grovesii* var. *lusitanicus*.
823 Later, Martín-Closas et al. (2009) redefined this biozone as a total range biozone limited
824 between the FAD of *A. cruciata* and *P. paucibracteatus* and the last appearance datum
825 (LAD) of *P. paucibracteatus*. The redefinition as a partial range biozone in this paper
826 follows the original characterisation of the late Barremian *Asciidiella cruciata* partial
827 range biozone of Riveline et al. (1996) but using the FAD of *A. cruciata* and *P.*

828 *paucibracteatus*. This avoids possible problems of (1) overlapping between the
829 *Asciodiella cruciata*-*Pseudoglobator paucibracteatus* biozone and the overlying *Clavator*
830 *grovesii* var. *lusitanicus* biozone if the LAD of *P. paucibracteatus* is found to be
831 younger than the FAD of *C. grovesii* var. *lusitanicus* and (2) occurrence of an undefined
832 interval between the two biozones. Such poorly defined biostratigraphic intervals are
833 usually designed as interval biozones.

834 *A. trivolvis* var. *trivolvis* occurs in this biozone. However, it never forms
835 homogeneous populations but it is found associated with *A. trivolvis* var. *triquetra*,
836 which is the dominant variety in the *Cruciata*-*Paucibracteatus* biozone. Homogeneous
837 populations of *A. trivolvis* var. *trivolvis* are typical of the overlying *Clavator grovesii*
838 var. *corrugatus* biozone (Riveline et al. 1996). *Asciodiella iberica* var. *inflata* (Grambast-
839 Fessard) Martín-Closas has not been identified in the studied sections. However,
840 Martín-Closas (2000) reported it from beds interbedded with *Palorbitolina lenticularis*
841 in other sections from the Maestrat basin.

842 **Biostratigraphic correlations.** In the Subalpine Chains, *P. paucibracteatus* has
843 been observed in a marl level above a grainstone bed containing *Paleodictyoconus*
844 *cuvillieri*, *Paleodictyoconus actinostoma* and *Cribrellopsis neolongata* (Mojon, 1988).
845 Martín-Closas et al. (2009) found *P. paucibracteatus* in marl beds interbedded with
846 marine layers alongside an orbitolinid assemblage composed of *Orbitolinopsis kiliani*,
847 *O. cuvillieri*, *O. buccifer* and *Palorbitolina lenticularis*. These authors correlated this
848 assemblage with the Barremian ammonite biozones of *Toxancyloceras vandenheckii*,
849 *Gerhardtia sartousiana*, *Hemihoplites feraudianus* (now the upper subzone of
850 *Gerhardtia sartousiana* according to Reboulet et al. 2018), *Imerites giraudi* and
851 *Martelites sarasini*. In the Iberian Chain, *A. cruciata* has been repeatedly correlated
852 with *P. lenticularis* (Martín-Closas, 2000 and references therein).

853 **Calibration based on SIS.** In the Herbers-Mas de Petxí section, the FAD of *P.*
854 *paucibracteatus* occurs in a marl bed at the basal part of the Artoles Formation (sample
855 H124; Fig. 3B), which is located 5 m below the stratigraphic layer where sample OyH4
856 was collected (Fig. 3B). An $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of 0.707482 ± 0.000012 was obtained for this
857 oyster shell, translating into a preferred age of *c.* 129.70 Ma (+1.20/-0.50) (Table 2) for
858 the base of this biozone. No calibration is available yet for the top of the biozone.

859 **Age.** Late early Barremian–early Aptian.

860

861 **7.2. The Barremian-early Aptian Eurasian charophyte biozonation**

862 ***Atopochara trivolis* var. *triquetra* biozone**

863 **Definition.** Time interval defined between the FAD of *Atopochara trivolis* var.
864 *triquetra* and the FAD of *Hemiclavator neimongolensis* var. *neimongolensis*.

865 **Species assemblage (Family Clavatoraceae) in the basins of the Cretaceous**

866 **Tethyan Archipelago.** *Echinochara lazarii*, *Globator mallardii* var. *trochiliscoides*

867 (dominant over *G. maillardii* var. *biutricularis*), *G. maillardii* var. *biutricularis*,

868 *Clavator grovesii* var. *gautieri*, *Asciadiella stellata* var. *stellata*, *A. stellata* var. *lata*

869 (dominant over *A. stellata* s.s.), *A. triquetra*, *A. iberica* var. *iberica*, *Hemiclavator*

870 *adnatus*, *H. neimongolensis* var. *posticecaptus*, and *Pseudoglobator fourcadei*.

871 **Species assemblage (Family Clavatoraceae) in all the Eurasian basins.**

872 *Atopochara trivolis* var. *triquetra*, *Clavator harrisi* var. *dongjingensis*, *C. harrisii* var.

873 *harrisii* (dominant over var. *dongjingensis* and var. *reyi*) and *C. calcitrapus* var.

874 *jianglouensis*.

875 **Remarks.** Riveline et al. (1996) characterised it as a partial range biozone that

876 was defined between the FAD of *A. trivolis* var. *triquetra* and the FAD of *Asciadiella*

877 *cruciata* in the European biozonation. Due to the cosmopolitan distribution of *A.*

878 *trivolis* var. *triquetra* (Martín-Closas and Wang 2008), this biozone is redefined herein

879 as a Eurasian biozone, with its upper boundary modified to the FAD of *H.*

880 *neimongolensis* var. *neimongolensis*.

881 The FAD of *A. trivolvis* var. *triquetra* seems to occur at least in the late
882 Hauterivian, where it appeared to be associated with *A. trivolvis* var. *ancora* (Fig. 3A).
883 However, it is not until the base of the Barremian when *A. trivolvis* var. *triquetra*
884 formed homogenous populations. This criterion, i.e., the occurrence of homogeneous
885 populations of this anagenetic variety, was used here to define the base of the *A.*
886 *trivolvis* var. *triquetra* biozone.

887 **Biostratigraphic correlations.** *A. trivolvis* var. *triquetra* frequently appears with
888 *G. maillardii* var. *trochiliscoides* in the Iberian Chain (e.g., Combes et al. 1966, Martín-
889 Closas and Salas 1994, Martín-Closas 2000) and in the Subalpine Chains (Martín-
890 Closas et al. 2009). Thus, it has been correlated with the same orbitolinid species and
891 ammonite biozones as those for the *G. maillardii* var. *trochiliscoides* biozone.

892 **Calibration based on SIS.** The upper boundary of this biozone was calibrated in
893 the Fredes section with an $^{87}\text{Sr}/^{86}\text{Sr}$ ratio obtained from a low-Mg oyster shell belonging
894 to sample OyFr21c (Fig. 4 and Table 2). The $^{87}\text{Sr}/^{86}\text{Sr}$ value is 0.707481 ± 0.000012 ,
895 translating into a preferred numerical age of 129.80 Ma (+1.15/-0.60).

896 **Age.** Early Barremian.

897

898 **Hemiclavator neimongolensis** var. **neimongolensis** biozone

899 **Definition.** Partial range biozone defining the interval between the FAD of
900 *Hemiclavator neimongolensis* var. *neimongolensis* and the FAD of *Clavator grovesii*
901 var. *jiuquanensis*.

902 **Species assemblage (Family Clavatoraceae) in the basins of the Cretaceous**

903 **Tethyan Archipelago.** *Echinochara lazarii*, *Globator mallardi* var. *trochiliscoides*, *G.*
904 *maillardii* var. *biutricularis*, *Clavator grovesii* var. *combei*, *C. calcitrapus* var.

905 *calcitrapus*, *Asciidiella stellata* var. *lata*, *A. triquetra*, *A. cruciata*, *A. iberica* var. *inflata*,
906 and *Pseudoglobator paucibracteatus*.

907 **Species assemblage (Family Clavatoraceae) in all the Eurasian basins.**

908 *Atopochara trivolvris* var. *triquetra*, *Clavator harrisii* var. *dongjingensis*, *C. harrisii* var.
909 *harrisii* (dominant variety of this species), *C. harrisii* var. *reyi*, *C. calcitrapus* var.
910 *jiangluoensis*, and *Hemiclavator neimongolensis* var. *neimongolensis*.

911 **Remarks.** The base of the biozone is marked by the first homogeneous population
912 of *H. neimongolensis* var. *neimongolensis*. In the Herbers-Mas de Petxí section, mixed
913 populations of *H. neimongolensis* var. *posticecaptus* and *H. neimongolensis* var.
914 *neimongolensis* occur in the uppermost part of the *A. trivolvris* var. *triquetra* biozone
915 (e.g., samples H36–H38; Fig 3A), while the first homogeneous population of *H.*
916 *neimongolensis* var. *neimongolensis* occurs a few metres above (sample H39; Fig 3A).
917 The wide biogeographic range of *H. neimongolensis* var. *neimongolensis* and its quick
918 expansion from Iberia to China (Martín-Closas 2015) make this species a useful tool to
919 perform intercontinental correlations of non-marine successions.

920 Homogeneous populations of *C. calcitrapus* var. *jiangluoensis* can be found at the
921 base of the *Hemiclavator neimongolensis* var. *neimongolensis* biozone, while
922 homogenous populations of *C. calcitrapus* s.s. are found only in the upper part of the
923 biozone. In fact, the *C. calcitrapus* populations observed in the *H. neimongolensis* var.
924 *neimongolensis* biozone frequently contain both *C. calcitrapus* var. *jiangluoensis* and *C.*
925 *calcitrapus* s.s., as well as intermediate morphotypes.

926 **Calibration based on SIS.** The FAD of the index species in the Fredes section
927 occurs in sample Fr21c (Fig. 4) in association with oyster shells (sample OyFr21c;
928 Table 2). The $^{87}\text{Sr}/^{86}\text{Sr}$ value obtained for this sample is 0.707481 ± 0.000012 , which
929 gives a preferred age of 129.80 Ma (+1.15/-0.60).

930 **Age.** Late early Barremian–early late Barremian.

931

932 **Clavator grovesii var. jiuquanensis biozone**

933 **Definition.** Partial range biozone comprising the interval between the FAD of
934 *Clavator grovesii* var. *jiuquanensis* and the FAD of *Clavator grovesii* var. *corrugatus*.

935 **Species assemblage (Family Clavatoraceae) in the basins of the Cretaceous**
936 **Tethyan Archipelago.** *Echinochara lazarii*, *Globator maillardii* var. *trochiliscoides*, *G.*
937 *maillardii* var. *biutricularis* (dominant over var. *trochiliscoides*), *Ascidiella cruciata*, *A.*
938 *iberica* var. *inflata*, and *Pseudoglobator paucibracteatus*.

939 **Species assemblage (Family Clavatoraceae) in all the Eurasian basins.**

940 *Atopochara trivolvris* var. *triquetra* (dominant over var. *trivolvris*), *A. trivolvris* var.
941 *trivolvris*, *Clavator grovesii* var. *jiuquanensis*, *Clavator harrisii* var. *harrisii*, *C. harrisii*
942 var. *reyi* (dominant over var. *harrisii*), and *Hemiclavator neimongolensis* var.
943 *neimongolensis*.

944 **Remarks.** *C. grovesii* var. *jiuquanensis* was used by Wang and Lu (1982) to
945 define the Perimneste ancora–Clypeator jiuquanensis assemblage biozone (former
946 taxonomy for *Atopochara trivolvris* var. *ancora* and *C. grovesii* var. *jiuquanensis*,
947 respectively) with a Hauterivian-lower Barremian age range in the Chinese basins.
948 Similar ages were suggested for the Mesochara stipitata-Clypeator jiuquanensis-
949 Flabellochara hebeiensis assemblage biozone (the latter a synonym of *C. harrisii* var.
950 *harrisii*) defined by Peng et al. (2003). Yang et al. (2008) proposed a Clypeator
951 jiuquanensis biozone that characterized the Hauterivian and the Barremian. However,
952 recent data about the age of this taxon in China also suggest a late Barremian-early
953 Aptian age (Li et al. 2020), similar to the ages observed in Europe.

954 The *Clavator grovesii* var. *jiuquanensis* biozone comprises most of the
955 biostratigraphic interval of the European Crucata-Paucibracteatus biozone of Martín-
956 Closas et al. (2009). However, the Eurasian biogeographic range of *C. grovesii* var.

957 *jiuquanensis* and its quick spread throughout the entire Eurasian domain (Martín-Closas
958 2015) favours its use as a valuable index species to perform non-marine intercontinental
959 correlations with.

960 **Biostratigraphic correlations.** In the Subalpine Chains, *C. grovesii* var.
961 *jiuquanensis* occurs together with *P. paucibracteatus* (Martín-Closas et al. 2009),
962 indicating that the *C. grovesii* var. *jiuquanensis* biozone can be correlated with benthic
963 foraminifera and ammonite biozones similar to those used for the Cruciatia-
964 Paucibracteatus biozone.

965 **Calibration based on SIS.** The FAD of the index species is 24.5 m above the
966 oyster bed from where sample OyH6 was collected in the Herbers-Mas de Petxí section
967 (Fig. 3B). The $^{87}\text{Sr}/^{86}\text{Sr}$ of 0.707489 ± 0.000012 obtained with this sample translates
968 into a preferred age of 129 Ma (+0.80/-0.75).

969 **Age.** Late Barremian–early Aptian.

970

971 -----Please insert Fig. 6 near here-----

972

973 **8. Discussion**

974 **8.1. The Barremian-early Aptian charophyte biozonation revisited**

975 Two different Barremian–early Aptian charophyte biozonations, one for the
976 Cretaceous Tethyan Archipelago (European) and the other for the whole Eurasian
977 domain, are proposed herein (Fig. 6). The European biozonation is formed of index
978 species that are exclusive to Europe and North Africa, whereas the Eurasian biozonation
979 is composed of sub-cosmopolitan to cosmopolitan index species based on the
980 biogeographic studies of Martín-Closas and Wang (2008) and Martín-Closas (2015).

981 The new Barremian Eurasian biozonation proposed in this paper is composed of
982 three biozones that characterise (1) the early Barremian (the *Atopochara trivolvis* var.

983 triquetra biozone), (2) the late early Barremian–early late Barremian (the *Hemiclavator*
984 *neimongolensis* var. *neimongolensis* biozone) and (3) the late Barremian–early Aptian
985 (the *Clavator grovesii* var. *jiuquanensis* biozone), respectively. This provides a better
986 biostratigraphic resolution than the European and Chinese charophyte biozonations used
987 to date (e.g., Riveline et al. 1996, Martín-Closas et al. 2009 and Wang and Lu 1982,
988 Yang et al. 2008, respectively). This is surprising since high-resolution charophyte
989 biozonations are often regional, basin-wide to continent-limited (e.g., Sanjuan et al.
990 2014, Vicente et al. 2015, 2016 for Europe with regional subzones; Li et al. 2019 for
991 North China), while sub-cosmopolitan to cosmopolitan species usually usually have
992 lower evolutionary rates, resulting in less precise biostratigraphic subdivisions. For
993 instance, Li et al. (2016) proposed a late Campanian–late Maastrichtian Eurasian
994 *Microchara cristata* biozone, which was later considered a superzone and subdivided
995 into three regional Chinese biozones (Li et al. 2019).

996 The Eurasian *A. trivolvis* var. *triquetra* biozone is equivalent to the biozone with
997 the same index species described by Riveline et al. (1996) and Martín-Closas et al.
998 (2009), except that its upper boundary has been modified to the FAD of *H.*
999 *neimongolensis* var. *neimongolensis*. The *H. neimongolensis* var. *neimongolensis*
1000 biozone was originally proposed as a regional Iberian subzone for the upper part of the
1001 *Atopochara trivolvis* var. *triquetra* biozone by Martín-Closas and Salas (1994) and
1002 Martín-Closas and Schudack in Riveline et al. (1996). This subzone was first used to
1003 resolve biostratigraphic correlations within Iberia (Martín-Closas and Alonso-Millán
1004 1998), since the index species was unknown in other European basins. Later, it was
1005 reported to be present in the Subalpine Chains and Jura Mountains in France and
1006 Switzerland (Martín-Closas et al. 2009). It was already known to occur in China (Wang
1007 and Lu 1982).

1008 The *Hemiclavator neimongolensis* var. *neimongolensis* biozone directly correlates
1009 with the upper part of the *Globator maillardii* var. *trochiliscoides* European biozone and
1010 the base of the *Asciidiella cruciata*-*Pseudoglobator paucibracteatus* European biozone
1011 (Fig. 6), indicating that the charophyte assemblage of this biozone is composed of
1012 species from both European biozones (sections 7.1 and 7.2).

1013 *Clavator grovesii* var. *jiuquanensis* is the index species of the third Eurasian
1014 biozone (late Barremian–early Aptian). This species was previously used as an index
1015 species to characterise a Hauterivian–early Barremian biozone in Chinese basins (Wang
1016 and Lu 1982, Peng et al. 2003, Yang et al. 2008). However, more recent data from the
1017 Jiuquan Basin suggest a late Barremian–early Aptian (more probably early Aptian) age
1018 for this species (Li et al. 2020), based on a previous chemostratigraphic ($\delta^{13}\text{C}$ and $\delta^{18}\text{O}$)
1019 study performed by Suárez et al. (2013) and through comparisons with the age of *C.*
1020 *grovesii* var. *jiuquanensis* given by Martín-Closas et al. (2009) in Europe. The derived
1021 numerical ages obtained in the present study agree with the ages previously suggested
1022 for *C. grovesii* var. *jiuquanensis* in Eurasia.

1023

1024 **8.2. Comparison with other Barremian charophyte biozonations**

1025 The European Barremian biozonations proposed to date followed and modified
1026 the pioneering proposal by Grambast (1974), who defined two assemblage biozones, ‘El
1027 Mangraner’ (early Barremian) and ‘San Carlos’ (late Barremian), which were obtained
1028 after studying the clavatoracean succession in the Eastern Iberian Chain. These biozones
1029 were the base for the European or more local charophyte biozonations, such as those by
1030 Feist et al. (1995) and Riveline et al. (1996), which distinguished an early Barremian
1031 biozone and a late Barremian biozone. The biozonation by Riveline et al. (1996)
1032 changed the type of biozone from assemblage zones to partial range zones. The
1033 charophyte assemblages observed in successive European biozonations and also in the

1034 European biostratigraphic framework described herein are more diverse but include the
1035 assemblages described by Grambast (1974).

1036 Mojon (1996, 2002) questioned the age of these assemblages, suggesting that they
1037 were younger (late Barremian and early Aptian, respectively, M8a and M8b) and,
1038 therefore, created a third biozone for the early Barremian (M7b) based on a newly
1039 defined morphotype, *Globator trochiliscoides* subsp. *mutabilis* (Fig. 6). However, this
1040 proposal was based on a misinterpretation of the Barremian units of the Iberian Chain,
1041 as discussed by Martín-Closas and Salas (1998). Therefore, the age of these biozones
1042 given by Riveline et al. (1996) is now supported by the calibration of the charophyte
1043 assemblages performed with SIS in the present study. As a consequence, the two
1044 European biozones proposed herein, i.e., the *Globator maillardii* var. *trochiliscoides* and
1045 the *Ascidiella cruciata*-*Pseudoglobator paucibracteatus* biozones, can be largely
1046 correlated with the equivalent biozones of Riveline et al. (1996) (Fig. 6).

1047 Barremian charophyte biozonations have been proposed for two more regions,
1048 China and South America (Argentina). In China, two Barremian assemblage biozones
1049 were proposed by Wang and Lu (1982): the *Perimneste ancora*-*Clypeator jiuquanensis*
1050 and the *Atopochara trivolvis* *triquetra*-*Flabellochara hebeiensis* biozones. The age of
1051 these biozones was used as a reference for subsequent biostratigraphic proposals (e.g.,
1052 Peng et al. 2003, Yang et al. 2008). With the exception of *C. grovesii* var. *jiuquanensis*
1053 (= *Clypeator jiuquanensis*), which is now considered to date to the late Barremian-early
1054 Aptian (also in China according to Li et al. 2020), the association described within the
1055 *Perimneste ancora*-*Clypeator jiuquanensis* biozone has been documented in Europe
1056 through the *Globator maillardii* var. *steinhauseri* European biozone (see Riveline et al.
1057 1996), which dates to the latest Berriasian–late Hauterivian. By contrast, the
1058 clavatoracean assemblage described in the late Barremian Chinese *Atopochara trivolvis*
1059 *triquetra*-*Flabellochara hebeiensis* biozone (= *A. trivolvis* var. *triquetra* and *Clavator*

1060 *harrisii* var. *harrisii*, respectively) by Wang and Lu (1982) is comparable to the
1061 European *Globator maillardii* var. *trochiliscoides* biozone. The Chinese *Atopochara*
1062 *trivolis triquetra*-*Flabellochara heibeiensis* biozone is also characterised by the
1063 presence of *H. neimongolensis* var. *neimongolensis*, suggesting that this Chinese
1064 biozone includes the Eurasian *Atopochara trivolis* var. *triquetra* and *Hemiclavator*
1065 *neimongolensis* var. *neimongolensis* biozones proposed herein.

1066 In Argentina, a late Hauterivian–early Barremian *Atopochara trivolis triquetra*
1067 assemblage zone was proposed by Musacchio (1989, 2000). This biozone is
1068 characterised by the association of *A. trivolis triquetra* (= *A. trivolis* var. *triquetra*)
1069 with *Trichypella patagonica* Musacchio (synonym of *Clavator calcitrapus* var.
1070 *jiangluoensis*, see Pérez-Cano et al. 2020). The association of *A. trivolis* var. *triquetra*
1071 with *C. calcitrapus* var. *jiangluoensis* is observed in the European *G. maillardii* var.
1072 *trochiliscoides* biozone (section 7.1) and in the Eurasian *A. trivolis* var. *triquetra* and
1073 *H. neimongolensis* var. *neimongolensis* biozones (section 7.2), making the correlation
1074 between South American and Eurasian basins possible. A late Barremian biozone has not
1075 yet been characterised in South America. The Aptian South American *Flabellochara*
1076 *harrisii* (= *C. harrisii* var. *harrisii*) biozone distinguished by Musacchio (1989, 2000) can
1077 be partially correlated with the European *Asciella cruciata*-*Pseudoglobator*
1078 *paucibracteatus* biozone and with the Eurasian *Clavator grovesii* var. *jiuquanensis*
1079 biozone.

1080

1081 **8.3. Correlations with the marine realm**

1082 The $^{87}\text{Sr}/^{86}\text{Sr}$ ratios and derived numerical ages can be used to correlate
1083 charophyte assemblages with ammonite biozonations. This correlation was carried out
1084 by taking into account the $^{87}\text{Sr}/^{86}\text{Sr}$ values reported by different studies for the Tethyan
1085 and Boreal domains, as well as the standard $^{87}\text{Sr}/^{86}\text{Sr}$ curve found in the ‘LOWESS 5 fit

1086 26 03 13' look-up table of McArthur, which is tied to the numerical ages and ammonoid
1087 biozonation of the GTS2012 by Gradstein et al. (2012). However, the offset between the
1088 Boreal and Tethyan Barremian $^{87}\text{Sr}/^{86}\text{Sr}$ curves (see Mutterlose et al., 2014) makes the
1089 precise correlation between the Tethyan and Boreal domains difficult for this stage.

1090 The stratigraphically lowest sample analysed for SIS (OyFr21c) coincides with
1091 the FAD of *H. neimongolensis* var. *neimongolensis* in the Fredes section (Fig. 4) and,
1092 thus, with the base of the homonymous Eurasian biozone. The $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of this
1093 sample, 0.707481 (see Table 2), is similar to the $^{87}\text{Sr}/^{86}\text{Sr}$ ratios (0.707478 to 0.707483)
1094 reported from southern France by Bodin et al. (2009) between the upper part of the
1095 *Nicklesia pulchella* and the lower part of the *Kotetishvilia compressissima* ammonoid
1096 biozones. According to the Sr isotope curve tied to the GTS2012 used, this $^{87}\text{Sr}/^{86}\text{Sr}$
1097 ratio correlates precisely with the boundary between the *N. pulchella* and *K.*
1098 *compressissima* ammonoid biozones (Fig. 6). McArthur et al. (2004) reported $^{87}\text{Sr}/^{86}\text{Sr}$
1099 ratios of ~0.707476 to ~0.707485 for the early Barremian *Haplocrioceras fissicostatum*
1100 Zone of the Boreal region.

1101 The stratigraphically upper samples for SIS were obtained from the Artoles
1102 Formation in the Herbers-Mas de Petxí section. Sample OyH4 was obtained 5 metres
1103 above the FAD of *P. paucibracteatus* with a Sr isotope value of 0.707482, and was used
1104 to date the base of the *Asciidiella cruciata*-*Pseudoglobator paucibracteatus* biozone. A
1105 similar value of 0.707483 has been described for the lower part of the *K.*
1106 *compressissima* Tethyan ammonite biozone in south-eastern France (Bodin et al. 2009).
1107 In addition, plotting the Sr isotope value obtained from sample OyH4 against the
1108 standard Sr isotope curve from the GTS2012 revealed a correlation with the *K.*
1109 *compressissima* Zone. Hence, the Sr isotope data confirm the hypothesis of Martín-
1110 Closas et al. (2009), who indirectly correlated the base of the *Cruciata*-*Paucibracteatus*
1111 biozone with the middle part of the *Holcodiscus caillaudianus* ammonite biozone (late

1112 early Barremian). This ammonite biozone was relegated to a subzone inside the *K.*
1113 *compressissima* Zone in the most recent proposal of ammonite zonation for the West
1114 Mediterranean Province of the Tethyan Realm (Reboulet et al. 2018). The Sr isotope
1115 value obtained with sample OyH4 coincides with those of the *Haplocrioceras*
1116 *fissocostatum* ammonite biozone in the Boreal Realm (values from 0.707476 to
1117 0.707485; see McArthur et al. 2004).

1118 OyH6 was the youngest low-Mg sample used to derive the numerical ages in this
1119 study (Fig. 3B). The sample has an $^{87}\text{Sr}/^{86}\text{Sr}$ value of 0.707489 (Table 2), which
1120 corresponds to a period from late early Barremian to early late Barremian (*sensu* Wan et
1121 al. 2019). This period is associated with stable $^{87}\text{Sr}/^{86}\text{Sr}$ ratios (e.g., Jones and Jenkins,
1122 2001, McArthur et al. 2012, Mutterlose et al. 2014), making it difficult to obtain a
1123 precise numerical age within this interval. The Sr isotope value of sample OyH6 falls
1124 within the range (0.707485-0.707493) obtained by McArthur et al. (2004) for the
1125 *Paracrioceras elegans* ammonite biozone in the Boreal Realm. Bodin et al. (2009) and
1126 Huck et al. (2011) reported similar mean $^{87}\text{Sr}/^{86}\text{Sr}$ values for the Tethyan Realm as
1127 those found here for the *Moutoniceras moutonianum* ammonite biozone (latest early
1128 Barremian) and the base of the *Toxancyloceras vandenheckii* (earliest late Barremian)
1129 ammonite biozone. According to the Sr isotope curve tied to the GTS2012, the $^{87}\text{Sr}/^{86}\text{Sr}$
1130 value of sample OyH6 correlates with that of the early late Barremian Tethyan
1131 *Toxancyloceras vandenheckii* ammonite biozone (Fig. 6). However, sample OyH6 was
1132 obtained ~24.5 m below the FAD of *C. grovesii* var. *jiuquanensis* (Fig. 3B).
1133 Consequently, the base of the homonymous biozone may be younger than the numerical
1134 age obtained for this sample.

1135

1136 **9. Conclusions**

1137 Compiled biogeographic and biostratigraphic data on clavatoracean species, with
1138 a particular focus on its succession recorded in the Maestrat Basin, established two
1139 distinct charophyte biozonations (European and Eurasian) spanning the Barremian-early
1140 Aptian period. The European charophyte biozonation is composed of two biozones
1141 whose index species were endemic in the Cretaceous Tethyan Archipelago. Its
1142 application is currently restricted to present-day Europe and North Africa. The biozones
1143 correspond to the *Globator maillardii* var. *trochiliscoides* (early Barremian) and
1144 *Asciidiella cruciata*-*Pseudoglobator paucibracteatus* (late early Barremian–early Aptian)
1145 biozones. The novel Eurasian biozonation proposed here includes the *Atopochara*
1146 *trivolis* var. *triquetra* (early Barremian), *Hemiclavator neimongolensis* var.
1147 *neimongolensis* (late early Barremian–early late Barremian) and *Clavator grovesii* var.
1148 *jiuquanensis* (late Barremian–early Aptian) biozones. This new biostratigraphic
1149 proposal, whose index species are widely reported throughout Eurasia, aims to facilitate
1150 the correlation between distant continental basins (e.g., from China and Europe).

1151 Correlation between the continental and marine realms carried out using $^{87}\text{Sr}/^{86}\text{Sr}$
1152 values indicated that the age of the boundary between the *Globator maillardii* var.
1153 *trochiliscoides* and *Asciidiella cruciata*-*Pseudoglobator paucibracteatus* biozones of the
1154 European biozonation is roughly equivalent to that of the lower part of the Tethyan
1155 *Kotetishvilia compressissima* ammonoid biozone (c. 129.70 Ma). Regarding the
1156 Eurasian biozonation, the age of the base of the *Hemiclavator neimongolensis* var.
1157 *neimongolensis* biozone, which bounds the *Atopochara trivolis* var. *triquetra* biozone
1158 below, correlates with that of the boundary between the *Nicklesia pulchella* and
1159 *Kotetishvilia compressissima* ammonite zones (c. 129.80 Ma). The base of the *Clavator*
1160 *grovesii* var. *jiuquanensis* biozone is constrained to the upper part of the *Toxancyloceras*
1161 *vandenheckii* ammonoid Zone (c. 129.00–128.63 Ma).

1162 The five Barremian biozones described in this paper (including the European and
1163 Eurasian biostratigraphic frameworks) have been recognised in the stratigraphic
1164 succession studied in Herbers-Mas de Petxí. Therefore, we propose this sedimentary
1165 record cropping out in the northern Maestrat Basin to be the main reference section for
1166 Barremian charophyte biostratigraphy.

1167

1168 **Acknowledgements**

1169 This study was supported by project BIOGEOEVENTS (CGL2015-69805-P) via
1170 the Spanish Ministry of Economy and Competitiveness, the European Regional
1171 Development Fund (ERDF) and project 2017SGR-824 of AGAUR (Catalan Research
1172 Agency). The research was also supported by the predoctoral grant BES-2016-076469
1173 from the Spanish Ministry of Economy and Competitiveness to JP-C.

1174 Dr Alejandro Gallardo and Jordi Illa are acknowledged for their laboratory
1175 assistance during the sample processing. We would like to thank Francisco Menéndez,
1176 Rubén Martínez, and Maria Teresa González (CCiTUB) for their laboratory assistance
1177 during the OES-MS analysis. We are also grateful to José Manuel Fuenlabrada (CAI de
1178 Ciencias de la Tierra y Arqueometría, Universidad Complutense de Madrid) for his
1179 assistance with the isotope analysis. The authors are grateful to the editor Dr. Jochen
1180 Erbacher, the reviewer Dr. Alba Vicente (Estación Regional del Noroeste–Universidad
1181 Nacional Autónoma de México) and to an anonymous reviewer for their comments and
1182 the suggestions that significantly improved the manuscript. The English language of the
1183 manuscript was corrected by Michael Maudsley, University of Barcelona (Fundació
1184 Bosch i Gimpera, Universitat de Barcelona).

1508 Figure 1. A) Map of the main structural units of the Iberian Peninsula (modified
1509 from Salas et al. 2001). B) Palaeogeographical map of the Late Jurassic-Early
1510 Cretaceous syn-rift Maestrat and Garraf basins (modified from Salas et al. in Martín-
1511 Chivelet et al. 2019). SB, Sitges Sub-basin; EMB, El Montmell Sub-basin; EPB, El
1512 Perelló Sub-basin; SaB, Salzedella Sub-basin; OrB, Orpesa Sub-basin; PGB,
1513 Penyagolosa Sub-basin; CB, Cedramán Sub-basin; GB, Galve Sub-basin; LPB, Las
1514 Parras Sub-basin; OIB, Oliete Sub-basin; MoB, Morella Sub-basin. C) Geological map
1515 of the Herbers-Mas de Petxí area showing the location of the section logged (modified
1516 from Canérot and Leyva 1978). D) Geological map of the area of Fredes showing the
1517 location of the section logged (modified from García de Domingo and López-Olmedo
1518 1985).

1519 Figure 2. Lithostratigraphy of the uppermost Jurassic–Lower Cretaceous record of
1520 the Morella Sub-basin (after Salas et al. 2001, Bover-Arnal et al. 2016).

1521 Figure 3A. Stratigraphic log of the lower part of the Herbers-Mas de Petxí section
1522 showing the location from where the samples were obtained and the distribution of the
1523 charophyte species. Charophyte biostratigraphy follows the new biozonations presented
1524 here. Geographical and geological location shown in Fig. 1C. See Figure 5 for legend.

1525 Figure 3B. Stratigraphic log of the upper part of the Herbers-Mas de Petxí section
1526 showing the location from where samples were obtained and the distribution of the
1527 charophyte species. Charophyte biostratigraphy follows the new biozonations presented
1528 here. Geographical and geological location shown in Figure 1C. See Figure 5 for the
1529 legend.

1530 Figure 4. Stratigraphic log of the Fredes section. Charophyte biostratigraphy
1531 follows the new biozonations presented here. Geographical and geological location are
1532 shown in Figure 1D. See Figure 5 for the legend.

1533 Figure 5. Key for Figures 3A–B and 4.

1534 Figure 6. European and Eurasian Barremian charophyte biozones and their
1535 calibrated numerical ages. Numerical ages and geomagnetic polarity were obtained
1536 from Gradstein et al. (2012). Ammonite biostratigraphy was taken from Reboulet et al.
1537 (2018) and the age ranges for the ammonite biozones were obtained from Ogg and
1538 Hinnov (2012). The previous Barremian–early Aptian European biozones (Grambast
1539 1974, Feist et al. 1995, Mojon 1996, 2002, Riveline et al, 1996, Martín-Closas et al.
1540 2009) and Chinese biozones (Wang and Lu 1982, Yang et al. 2008) are compared with
1541 those proposed in the present study, considering only the charophyte biozones and the
1542 age given by the different studies and not the absolute ages. The correlation with
1543 ammonite biozones was only well-established by Riveline et al. (1996) and Martín-
1544 Closas et al. (2009). The dashed line in the Eurasian *C. grovesii* var. *jiuquanensis*
1545 biozone (present study) represents the maximum numerical age of this biozone.

1546

1547 Table 1: Charophyte species identified in the Herbers-Mas de Petxí and Fredes
1548 sections (the Morella Sub-basin). Letters A-H and A-E are referring to the intervals
1549 described in sections 5.1 and 5.2. L: Laterite.

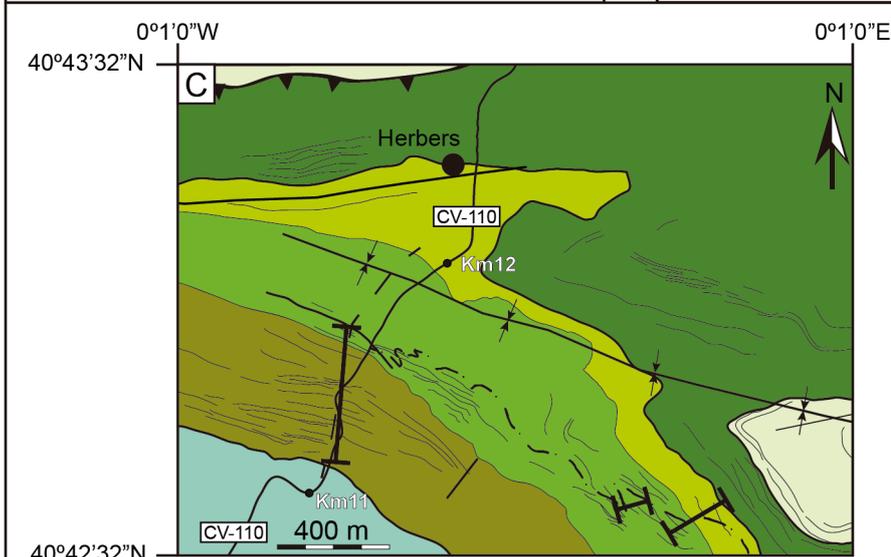

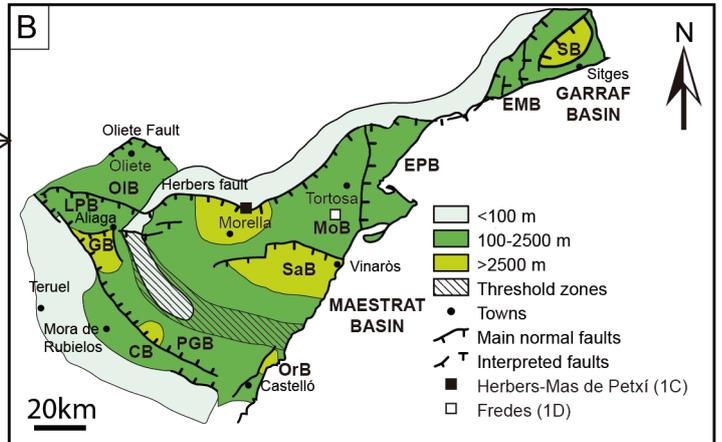

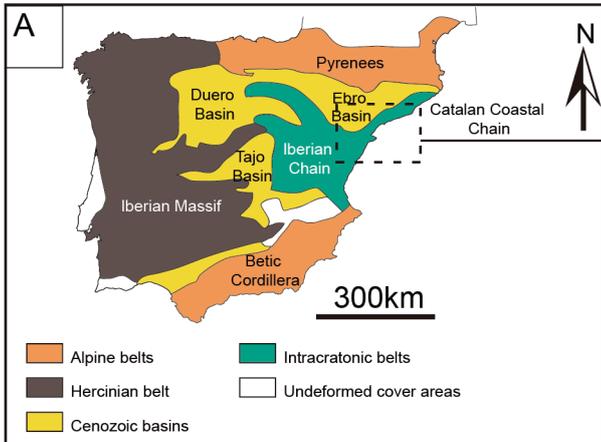

1550 Table 2. Analytical results and the derived numerical ages obtained from the low-
1551 Mg calcite oyster shells analysed in the present study. See Figures 3A–B and 4 for the
1552 location from where the analysed samples were obtained. The numerical ages follow
1553 those of Gradstein et al. (2012) and are derived from the ‘LOWESS 5 fit 26 03 13’
1554 look-up table by McArthur, and those of Gradstein et al. (2020) derived from the
1555 ‘LOESS 6 16 03 2020’ by McArthur (personal communication, 2021). ± 2 s.e., standard
1556 error; N.A., not analysed; Deg.Alt., degree of alteration; D.Alt., diagenetically-altered;
1557 Fr.Alt., freshwater-altered; N.Alt., non-altered. Samples and the analytical results used
1558 to derive the numerical ages are shown in bold.
