1	Abstract
2	We present ACACIA, an agent-based program implemented in Java
3	StarLogo 2.0 that simulates a two-dimensional microworld populated by agents,
4	obstacles and goals. Our program simulates how agents can reach long-term goals
5	by following sensorial-motor couplings (SMCs) that control how the agents
6	interact with their environment and other agents through a process of local
7	categorization. Thus, while acting in accordance with this set of SMCs, the agents
8	reach their goals through the emergence of global behaviors. This agent-based
9	simulation program would allow us to understand some psychological processes
10	such as planning behavior from the point of view that the complexity of these
11	processes is the result of agent-environment interaction.
12	
13	

14 Key words: agent-based simulation, long-term goals, local categorization

1	ACACIA: An agent-based program for simulating behavior to reach long-term
2	goals
3	In the last years, some approaches state that behavior emerges from the
4	interaction of the organism with the environment (Bakker, 2000; Brooks, 1999;
5	Holland, 1995; Maes, 1997; Meyer & Guillot, 1991). In fact, many complex
6	global behavioral events emerge from decentralized, independent components that
7	interact among them and with the local environment. Some examples include
8	traffic jams (Resnick, 1994), coordinated motion group such as bird flocking
9	(Reynolds, 1993), herds (Werner & Dyer, 1992), pedestrian behavior
10	(Schreckenberg & Sharma, 2002), and robots collecting objects (Maris & te
11	Boekhorst, 1996). In all those systems, a set of local rules is organized in terms of
12	the actions to be performed in order to respond to the circumstances of the
13	immediate environment. These local rules, defined as sensory-motor couplings by
14	Braitenberg (1984), guide the organism-environment interaction.
15	The aim of the agent-based simulation approach is to emulate the behavior
16	of natural organisms in complex, dynamic environments. By creating an artificial
17	agent able to perform certain behaviors in a virtual environment, it is possible to
18	try to determine the internal mechanisms underlying these behaviors. We present
19	ACACIA, an agent-based simulation program that simulates a multi-agent system
20	where agents interact with their environment and other agents in order to reach
21	long-term goals (Zibetti, Quera, Beltran & Tijus, 2001), which are defined here as
22	places that are desirable for the agents and that may be some distance away. The
23	program shows how the agents can reach a long-term goal based on a set of SMCs
24	that controls the agent's local interaction with its environment and with other
25	agents. The set of SMCs does not specify a global internal representation of the

1	environment or a sequence of steps necessary to reach the goal; rather, it is a
2	process of local categorization that determines how the agent relates locally with
3	objects and other agents in its environment (Zibetti, Quera, Tijus & Beltran,
4	2001). Thus, through the SMCs the agent groups and differentiates the entities in
5	its environment based both on their physical properties and on the task the agent
6	must perform. In the next sections, we show how de program works, some
7	previous results using the program and an example of a simulation experiment
8	that illustrates ACACIA's abilities.
9	The ACACIA Program
10	ACACIA is implemented in StarLogo (Colella, Klopfer & Resnick, 2001;
11	Resnick, 1994), a programmable environment designed to model multi-agent
12	simulation systems. It was developed using the Java StarLogo 2.0 version, which
13	runs on different operating systems, including Windows, Mac OS and Linux. The
14	program simulates a discrete, two-dimensional microworld that can be either a
15	torus or a closed space surrounded by walls. In both cases, the surface is divided
16	into 50 x 50 square cells (or patches). The microworld contains three different
17	kinds of entities: goals, obstacles, and agents (see Figure 1).
18	Goals
19	Goals are static entities that are sought by agents. Goals are shown red on
20	the screen and each one occupies one patch, or location. When the simulation
21	starts, goals are scattered randomly throughout the microworld. The number of
22	goals can vary from 1 to 20 and is set by the user.
23	Obstacles
24	Obstacles are areas composed of many contiguous patches that cannot be
25	occupied by agents and which agents cannot see through. Obstacles are shown

1 yellow on the screen, and are randomly distributed throughout the microworld,

2 their number (0 to 20) and shape (regular or irregular) being set by the user.

3 Agents

Agents have two-dimensional coordinates that specify their positions at 4 time t, and headings that indicate the directions of their movements. An agent can 5 move one cell or patch per time unit in any direction relative to its current 6 7 position. An agent's heading is defined as the angle between the linear path that links its positions at times t-1 and t and the X, or horizontal, axis of the 8 microworld. Initially, agents can be assigned either random headings or an 9 identical heading for all of them. Agent coordinates are initially set at random. 10 Agents can scan their neighborhood in order to identify different kinds of entities 11 (goals, obstacles, and other agents) that they might encounter while exploring the 12 13 environment. This mechanism has three parameters: (a) neighborhood radius, or depth of the agent's field of perception; (b) neighborhood angle, or width of the 14 15 agent's field of perception; and (c) scan resolution, which specifies how precise the agent's perception is within its neighborhood. The higher the resolution the 16 greater the number of patches the agent can scan. The three parameters define a 17 dynamic perceptual field in front of each agent so that only goals, other agents, 18 and obstacles that lie in that field can be currently perceived by it. 19 Depending on the entities currently detected by an agent, its "internal" 20 status can change. Agent statuses are represented by different colors on the 21 computer screen. Initially, at time t = 1, the status for all the agents is "explorer", 22 as they explore the environment looking for goals, and are shown green; 23

eventually, explorer agents may turn magenta, brown or orange as they perceive

25 other agents or obstacles. When an agent reaches a goal, its status changes to

"rich", and it is shown blue. Rich agents do not react to other entities; instead, 1 2 they keep moving straight ahead in a random direction from the patch where the previous goal was located until they encounter an obstacle or a wall, then they 3 disappear from the microworld because they have already reached the goal. The 4 reason why rich agents do not disappear as soon as they reach the goal is that we 5 felt this new information could be used by the other agents to reach it as well. If 6 7 different entities are simultaneously detected in the neighborhood, then goals have priority over agents, and agents have priority over obstacles. 8

An explorer agent has five hierarchical SMCs that allows it to respond 9 10 differently to the entities in the environment: (a) SMC-I: If an agent is exploring the environment and it detects a goal, then the agent sets the coordinates of the 11 goal as its target location, and moves one patch forward; agents applying this 12 13 SMC are are shown magenta. (b) SMC-II: If an agent is exploring and it detects a rich agent in its neighborhood, then the former sets its heading opposite to that of 14 15 the rich agent, then moving one patch forward; moving in a direction opposite to that of a rich agent may be a successful behavior because the rich agent is coming 16 from a goal; agents applying SMC-II are shown orange. (c) SMC-III: If an agent 17 is exploring and detects another explorer agent in its neighborhood, then the 18 former first checks whether their headings are similar (within a tolerance limit 19 defined by the user) and, if so, it sets its new heading so that it is the same as that 20 of the latter, and then moves one patch forward; moving in the same direction as 21 another explorer agent that is ahead may be a successful behavior because the 22 latter might have already seen a goal and be heading toward it; agents applying 23 SMC-III are shown brown. (d) SMC-IV: If an obstacle or a wall is detected, the 24 agent first checks whether it had already detected an obstacle or a wall in the 25

1	previous simulation step. If not so, it changes its heading 90° randomly to the left
2	or to the right; if an obstacle or a wall was detected in the previous step, then the
3	agent changes its heading 90° to the left if it had previously changed it to the left,
4	or 90° to the right if it had previously changed it to the right; in both cases, the
5	agent then moves one patch forward, provided there is no obstacle or wall in the
6	pacth to be occupied. Finally, (e) SMC-V: If no entity is detected, the agent
7	simply moves forward one patch following its heading and continues exploring;
8	agents applying SMC-V are shown green.
9	The user can selectively set on or off SMCs II, III and IV for all explorer
10	agents while the simulation is running. If the three SMCs are set on and an
11	explorer agent simultaneously meets a rich agent, an explorer agent and an
12	obstacle, SMC-II has priority over SMC-III and SMC-IV.

1	The simulation dynamics vary depending on the microworld parameters.
2	In previous experiments, we found that when the agents' perceptual ability was
3	limited by defining a neighborhood radius equal to 10 patches, setting SMC-III on
4	enabled agents to reach the goal. Moreover, a collective searching behavior
5	emerged, whereby agents followed each other. Note that no specific SMC for the
6	agents defined such collective searching behavior (Miñano & Beltran, 2004). We
7	also found that SMC-II (whereby agents headed in the opposite direction when
8	they met rich agents) also increased the probability of reaching the goal. As more
9	agents reached the goal, there were more opportunities for the other agents to see
10	them and to act in accordance with SMC-II. Thus, the activation of SMC-II
11	produced an emergent global migration of the agents to the goal. Nevertheless,
12	this collective migration was not specified in an SMC (Miñano & Zibetti, 2005).
13	In summary, we observed that the limited perceptual features of the agents
14	were compensated by a collective behavior emerging from the activation of SMC-
15	II and/or SMC-III. Like other computer models (Couzin, Krause, James, Ruxton
16	& Franks, 2002; Epstein & Axtell, 1996; Hemelrijk, 1996, 2003), local interaction
17	among agents results in cognitive optimization, i.e., "collaboration" among
18	individuals enables agents to create global patterns of collective behavior that
19	allow every individual agent to achieve its adaptive aims (Kennedy & Eberhart,
20	2001). Based on our previous results and in order to illustrate the ACACIA
21	features, we tried to find out whether setting SMC-III on also compensated for the
22	disadvantage of having a narrower neighborhood angle.
23	Method
24	We performed a series of simulations. For each simulation, we set 1 goal

and 50 randomly distributed agents, with a neighborhood radius of 10 patches and

1	a scan resolution of 10 scan lines. We systematically varied the independent
2	variables according to a three-factor design: 2 (SMC-III on or off) x 2 (angle: 120°
3	or 180°) x 2 (0 or 5 obstacles). 160 independent simulations were run for each
4	design cell, thus there were 1280 simulations in all. We measured the percentage
5	of agents that reached the goal after 400 simulation steps as a dependent variable.
6	Results and Discussion
7	An analysis of variance was performed on the percentage of agents that
8	reached the goal. The results showed statistically significant effects for the three
9	main factors: (a) when the neighborhood angle was set to 180°, a greater
10	percentage of agents reached the goal than when it was set to 120° (M=40.32 and
11	M=34.54, respectively; $\underline{F}_{1,1272}$ =45.45, \underline{p} <.0001); (b) a higher percentage of agents
12	reached the goal when SMC-III was on than when it was off (M=41.84 and
13	M=33.02, respectively; $\underline{F}_{1,1272}$ =105.78, \underline{p} <.0001); and (c) the presence of obstacles
14	decreased the percentage of agents reaching the goal, compared with when there
15	were no obstacles (M=32.01 and M=42.85, respectively; $\underline{F}_{1,1272}$ =159.78, \underline{p} <.0001).
16	The analysis of variance also indicated statistically significant effects between
17	neighborhood angle and number of obstacles ($\underline{F}_{1,1272}=5.20$, $\underline{p}<.05$), but not
18	between neighborhood angle and SMC-III, between SMC-III and number of
19	obstacles, and between the tree factors.
20	The results show that a neighborhood angle of 180° increased the agents'
21	chances of reaching the goal, even when the complexity of the environment was
22	increased to 5 obstacles. When SMC-III was set on results in an increase of the
23	number of the agents reaching the goal. Nevertheless, contrarily to what we
24	expected, the perceptual disadvantage of the agents with a neighborhood angle of
25	120° was not compensated by setting SMC-III on. However, some results of this

1	simulation experiment confirmed previous findings, specifically, that endowing
2	the agents with SMC-III (Miñano & Beltran, 2004).
3	Final Comments
4	We have shown that in some cases it is possible to reach a long-term goal
5	through the collective behavior that emerges from a set of sensorial-motor
6	couplings, and it is not necessary for the agent to generate an overall
7	representation of its environment. Thus, self-organized cognition based on a set of
8	sensorial-motor couplings could show a promising way to implement complex
9	behavior and reasoning. Therefore, in a future version, in order to improve the
10	performance of the ACACIA agents, they should build on their knowledge
11	through learning (as they would be initially naïve about their environment), which
12	could be made possible, for example, by implementing a learning-classification
13	system in each agent (Holland, 1995). Other features to be included in future
14	versions are individual differences in the agents' learning and perception,
15	perception errors (e.g., agents could mistake goals for obstacles) and inter-agent
16	communication.
17	Availability
18	ACACIA can be downloaded from
19	www.ub.es/comporta/gcai/Paginas/gcai_Downloads.htm. To run it on Windows,
20	Java Runtime Environment and StarLogo 2.21 must be preinstalled. StarLogo

21 2.21 can be downloaded from <u>http://education.mit.edu/starlogo/</u>.
