

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

Antidiabetic treatment and COVID-19 Outcomes: A population-based cohort study in primary health care in Catalonia during the first wave of the pandemic

ABSTRACT

Aims: To analyse if antidiabetic treatment was associated with better COVID-19 outcomes in type 2 diabetic patients, measured by hospital admission and mortality rates as severe outcomes.

Methods: Cohort study including COVID-19 patients registered in the Primary Care electronic records, in March–June 2020, comparing exposed to metformin in monotherapy with exposed to any other antidiabetic. Data source: SIDIAP (Information System for Research in Primary Care), which captures clinical information of 5,8 million people from Catalonia, Spain.

Results: We included 31,006 diabetic patients infected with COVID-19, 43.7% previously exposed to metformin, 45.5% of them in monotherapy. 16.4% were admitted to hospital and 15.1% died. Users of insulin in monotherapy (OR 1.29, 95% CI 1.11–1.50), combined with metformin (OR 1.38, 1.13–1.69) or IDPP4 alone (OR 1.29, 1.03–1.63) had higher risk of severe outcomes than those in metformin monotherapy. Users of any insulin (OR 1.61, 1.32–1.97) or combined with metformin (OR 1.69, 1.30–2.20) had a higher risk of mortality.

Conclusions: Patients receiving metformin monotherapy in our study showed a lower risk of hospitalization and death in comparison to those treated with other frequent antidiabetic agents.

We cannot distinguish if better outcomes are related with the antidiabetic therapy or with other factors, such as metabolic control or interventions applied during the hospital admission.

1. Introduction

Coronavirus disease 2019 (COVID-19) is a viral respiratory illness caused by the severe acute respiratory syndrome-coronavirus-2 (SARS-CoV-2) that emerged as a global public health crisis in 2020 [1–3] and it

is significantly associated with worse outcomes in people with chronic conditions, such as diabetes [4].

A series of inflammatory markers have been identified in diabetic patients, pointing out that this disease could be a risk factor for the progression and prognosis of COVID-19 [5]. Different mechanisms could

increase the risk and the severity of COVID-19 among diabetic patients, for instance the decrease in T CD4 positive cells, [6] the increase of interleukin-6 expression, or the positive regulation of the expression of angiotensin-2 converting enzyme (ACE2), [5] as SARS-CoV-2 can infect host cells by means of interaction with membrane-bound ACE2 on the respiratory epithelium [7].

As coronaviruses also bind dipeptidyl peptidase 4 (DPP4), [8] the interaction of SARS-CoV-2 and DPP4 may represent a potential factor promoting the virulence of the virus, and thus the inhibition of this interaction might curb the inflammatory storm seen in patients with severe COVID-19 [9,10]. DPP4 inhibitors (iDPP4) are highly selective hypoglycaemic agents which increase the bioavailability of the glucagon-like peptide-1 (GLP1) and have anti-inflammatory and

immunoregulatory effects, therefore, they could be useful to prevent COVID-19 fatal outcomes or improve the course of the disease in diabetic patients [11,12].

Other antidiabetic drug, metformin, has also anti-inflammatory activity and could be beneficial in treating COVID-19 at multiple levels by improving glucose controls, reducing insulin resistance, or suppressing mitochondrial reactive oxygen species. [13] Significant reduction in mortality has been reported among high-risk diabetic COVID-19 patients treated with metformin, so it may play a role in attenuating COVID-19 complications [14,15]. Other oral antidiabetic agents might be able to bind SARS-CoV-2 receptor (repaglinide, canagliflozin, glipezide, gliquidone, glimepiride and linagliptin), suggesting a possible inhibition of the replication and transcription of the virus [16]. Also GLP1 analogues have been suggested as possible candidates to treat COVID-19 for their anti-inflammatory and anti-obesogenic properties, pulmonary protective effects and benefits on gut microbiome, [17] or insulin for its anti-inflammatory effects [18].

Related with the use of antidiabetic drugs, in studies conducted with diabetic patients with COVID-19, a poor control of blood glucose levels have been associated with higher mortality in comparison with those with optimal metabolic control [19,20]. Although type 2 diabetes does not increase the susceptibility against SARS-CoV-2 infection, it can worsen the outcomes of the infection, particularly in those people with acute and chronic conditions. [4,21] Nevertheless, there are no guidelines focused on the treatment of COVID-19 in diabetic patients [22].

In this study we aimed to analyse if antidiabetic agents might be associated with a reduction in COVID-19 complications in diabetic patients, measured by hospital admission and mortality rates as severity outcomes, through a population-based cohort study including type 2 diabetes patients attended in Primary Health Care (PHC) who were infected with COVID-19 in Catalonia, Spain.

2. Methods

2.1. Study design

Cohort study including adult patients with COVID-19 diagnosis registered as confirmed (by polymerase chain reaction, PCR) or as probably (not confirmed by PCR) in the PHC records in Catalonia, Spain; from the pandemics' onset (March 2020) to June 30th, 2020. We compared type 2 diabetic patients with a diagnosis registered in the PHC records who were exposed to metformin in monotherapy with those exposed to any other antidiabetic drugs alone or in combination or those not receiving any antidiabetic agent.

2.2. Data source

The study data source is the Information System for Research in Primary Care (SIDIAP), [23,24] which captures clinical information of approximately 5,8 million people from Catalonia, Spain (around 80% of the Catalan population). This information is pseudonymized, originated from different data sources: 1) ECAP (electronic health records in PHC of the Catalan Health Institute); including socio-demographic characteristics, residents in nursing homes/long-term care facilities (LTCF), comorbidities registered as International Classification of Disease (ICD)– 10 codes, [25] specialist referrals, clinical parameters, toxic habits, sickness leave, date of death, laboratory test data, and drug prescriptions issued in PHC, registered as anatomical, chemical classification system (ATC) codes; [26] 2) pharmacy invoice data corresponding to the PHC drug prescriptions; 3) database of diagnoses at hospital discharge [27] and 4) COVID-19 data from the Catalan Agency of Health Quality and Evaluation (AQuAS). [28].

2.3. COVID-19 classification

Subjects were classified according to the following criteria:

Fig. 1. Frequencies of exposure to antidiabetic drugs in monotherapy and in combination. This figure shows the 30 most frequent antidiabetic treatments, in monotherapy and in combinations of up to 4 different drugs. The bars are ordered along the X-axis from highest to lowest frequency. GLP1; glucagon-like peptide-1 analogues, iDPP4; dipeptidyl peptidase 4 inhibitors, iSGLT2; sodium-glucose co-transporter 2 inhibitors.

confirmed cases were those with a confirmed COVID-19 diagnostic record, PCR+ and/or a positive serology test. Those with a non-confirmed diagnosis or test (possible or unclear) along with any individual with a record of hospitalization, pneumonia and/or death related to COVID-19 were considered possible cases. During the first wave of the COVID-19 pandemics in Catalonia, PCR tests were not routinely conducted to all patients with compatible symptoms, due to the unavailability of laboratory kits to do the tests. Thus, we needed to capture those patients with possible diagnosis of COVID-19, such as those admitted to hospital with pneumonia or other COVID-19 symptoms who were not tested. We designed an algorithm to classify patients as “COVID possible” when there was not a test result available. The date of COVID-19 diagnosis was set to be the first record used per patient.

To guarantee that our algorithm is not far from the Catalan population, the resulting cohort was compared to the official COVID-19 cases provided by the AQUAS during the pandemic [28,29].

2.4. Drug exposure

Patients were classified as exposed to metformin or other antidiabetics when they had at least one prescription issued during the previous 6 months to the COVID-19 diagnosis and with a minimum duration of 30 days. Those diabetic patients not meeting this criterion were considered as untreated. The reference group was composed by those people exposed to metformin in monotherapy.

The rest of the antidiabetic agents were classified as: insulins, sulfonylureas, iDPP4, sodium-glucose co-transporter 2 inhibitors (iSGLT2), GLP1 and other hypoglycaemic agents excluding insulins (HNI), including acarbose, pioglitazone or repaglinide.

2.5. Variables

At baseline, the variables captured were sex, age, body mass index

(BMI), residence in LTCF, smoking habit, glycated haemoglobin (HbA1c) measured up to 6 months before COVID-19 infection, years since type 2 diabetes diagnosis, comorbidities (ICD-10 codes), and drug exposure (ATC codes).

Main severity outcomes: rates of hospital admission and mortality. The risk of these events was analysed comparing patients exposed to metformin with those non-exposed to metformin (but with exposure to any other antidiabetic drug).

2.6. Statistical analysis

Quantitative variables were described as the mean and standard deviation or median and interquartile range, whereas categorical variables were described as the proportion over the exposed and non-exposed individuals. Univariate analyses were based on Student’s t-test or Chi-square test depending on the variable type.

For each outcome, composite severe event and death related to covid-19 infection, we fitted a logistic regression model to estimate an odds ratio (OR) comparing the prevalence of each outcome among individuals exposed to metformin monotherapy (reference population) to those exposed to other antidiabetic treatments or not being treated. The logistic model was fitted including other covariables such as gender, age, obesity, smoking habits, HbA1c at index date, history of diabetes, comorbidities, and concomitant drugs. Variable selection was performed using the AIC-based stepwise backward procedure and we used the Wald test on the fitted coefficient to determine whether the log-odds was significantly different from zero at a 0.05 level. All analyses were performed in R software (v4.1.0 or above).

3. Results

We included 31,006 people with type 2 diabetes who were infected with SARS-CoV-2 from March to June 2020, 21,131 (68.2%) were

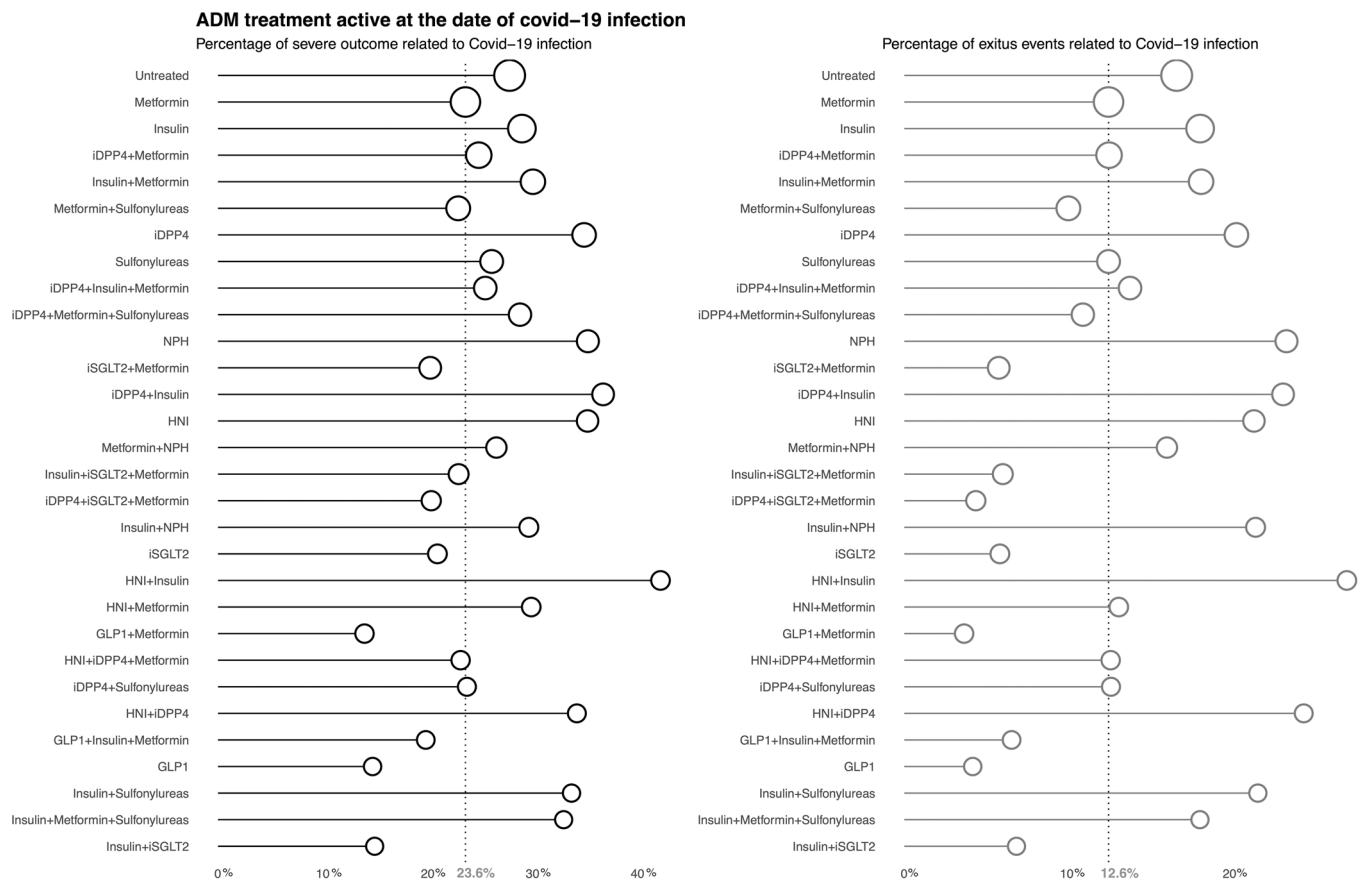

Fig. 2. Frequency of severe outcomes of the COVID-19 infection per antidiabetic treatment: a) Any of the severe outcomes; hospitalization or mortality. b) Mortality. Fig. 2 shows the frequency of events per antidiabetic treatment. The vertical dotted line corresponds to the frequency of events in those under metformin monotherapy. The treatments showed are the 30 most frequent ones and include: GLP1; glucagon-like peptide-1 analogues, iDPP4; dipeptidyl peptidase 4 inhibitors, iSGLT2; sodium-glucose co-transporter 2 inhibitors, HNI; other hypoglycaemic agents, non-insulin.

receiving treatment with antidiabetic drugs and 13,549 (43.7%) of them were exposed to metformin. There were more diabetic men (15,903, 51.3%) than women, the mean age of all patients included was 71.5 years-old and 50.9% were current smokers. The most frequent comorbidities were hypertension (71.1%), obesity (57.2%) and respiratory diseases (38.2%), and the most prescribed comedications were psychotropic drugs (52.0%), non-steroidal anti-inflammatory drugs (43.9%), and angiotensin converting enzyme inhibitors (30.1%). Table 1 shows the baseline characteristics for all population and for those receiving metformin in monotherapy.

The exposure to antidiabetic drugs is described in Table 2; 56.7% of the antidiabetic drugs' users were treated in monotherapy. The most used pharmacological groups were metformin (64.1%), insulins (26.4%) and iDPP4 (24.3%). The most frequent drugs in monotherapy and in combination are shown in Fig. 1.

At least one of the main outcomes of the study occurred in 8035 (25.9%) diabetic patients: hospitalization in 5096 (16.4%) and death in 4678 (15.1%). In Fig. 2 we present the frequency of events (in percentage) per antidiabetic treatment. Vertical dotted line shows the frequency of events in those under metformin monotherapy, the reference group. Treatments with the circle on the right of the line, as untreated, treated with insulin monotherapy, with metformin plus iDPP4, or with a combination of insulin and metformin showed higher frequencies of severe events in comparison to the reference drug.

Fig. 3 shows the risk of severe outcomes per antidiabetic treatment. Those patients treated with insulins alone (OR 1.29, 1.11–1.50) or in combination with metformin (OR 1.38, 1.13–1.69), or iDPP4 alone (OR 1.29, 1.03–1.63) had a significant higher risk of experiencing any of the severe outcomes than those in metformin monotherapy. For untreated,

the results were not statistically significant (OR 1.09, 95% CI 0.98–1.22). Other less frequent combinations showed significant higher risk of hospitalisation or death than metformin; metformin + sulfonylureas + either iDPP4 or /insulin, or insulin plus other hypoglycaemic drugs.

Those receiving any insulin alone (OR 1.61, 1.32–1.97) or insulins combined with metformin (OR 1.69, 1.30–2.20) had a higher risk of mortality than those in metformin monotherapy. Other less common combinations showing a higher mortality risk were metformin + sulfonylurea + insulin and insulin + GLP1.

4. Discussion

We analysed the outcomes of COVID-19 infection in 31,006 diabetic patients, comparing those chronically treated with metformin with those treated with other antidiabetic drugs. In our population, patients receiving only insulin, insulin combined with metformin or iDPP4 in monotherapy had a higher risk of experiencing hospitalization or death in comparison with people treated with metformin in monotherapy.

A recent study published in Spain analysed the sociodemographic, clinical and analytical variables associated with the need for hospital admission due to COVID-19 complications in a PHC cohort and specifically assessed whether diabetes entailed higher risk, finding that it did not increase risk of hospitalization in this population (OR 1.18, 95% CI 0.80–1.72) [30].

Different antidiabetic drugs have been studied for their anti-inflammatory properties and other effects which could help improving COVID-19 complications in diabetic patients from different settings. Yang W. et al. conducted a meta-analysis of 17 studies including 20,719

Fig. 3. Risk of the severe outcomes per antidiabetic treatment: a) Any of the severe outcomes; hospitalization or mortality. b) Mortality. The treatments showed are the 30 most frequent ones and include: GLP1; glucagon-like peptide-1 analogues, iDPP4; dipeptidyl peptidase 4 inhibitors, iSGLT2; sodium-glucose co-transporter 2 inhibitors, HNI; other hypoglycaemic agents, non-insulin. OR and 95% CI, adjusted.

COVID-19 diabetic patients and found that metformin could benefit mortality and severity (OR 0.64, 95% CI 0.51–0.79; and OR 0.81, 95% CI 0.66–0.99, respectively) [31]. In our study, we found lower risk of severe outcomes for patients receiving metformin in monotherapy when compared to other antidiabetic treatments, as insulin alone or associated to metformin, or iDPP4, but not comparing with other treatments.

Chen Y et al. performed a meta-analysis of 35 studies and found that

metformin, iDPP4, iSGLT2 and GLP1 (OR 0.74, 0.88, 0.82 and 0.91, respectively) were highly possible to reduce mortality risk and insulin might be related to increased mortality risk (OR 1.8) [32]. We also found a higher mortality risk with insulin.

In another review of 61 studies analysing pre-admission medication, the authors found protective effect against COVID-related death with metformin, GLP1, and iSGLT2 (OR 0.54, 0.50 and 0.60, respectively);

and users of iDPP4 and insulin (OR 1.23 and 1.70) were more likely to die during hospitalization [33].

Metformin and sulfonylureas were studied in another meta-analysis including 18 studies with 17,338 patients, which found that both drugs were associated with lower mortality risk in COVID-19 diabetic patients (OR 0.69, 95% CI 0.55–0.86 for metformin and 0.80, 95% CI 0.66–0.96 for sulfonylureas) [34].

With regards to iDPP4, this meta-analysis also found that mortality was not different between users and non-users (OR 0.72, 0.51–1.01) [34]. Yang Y. et al. pooled the results of four articles to investigate if iDPP4 had a protective effect on the progression of COVID-19, and they found an improvement in the mortality risk in iDPP4 users (OR 0.58, 95% CI 0.34–0.99) [35]. Patoulias et al. found that these drugs administered during hospital admission decreased the risk for COVID-19-related death by 50% [36]. We found divergent results for this pharmacological group, with a higher risk of hospital admission or death in comparison with metformin users.

Regarding the insulins, the meta-analysis of Kan et al. mentioned above found that patients treated with insulin exhibited greater mortality (OR 2.20, 1.34–3.60) [34]. Other studies found negative outcomes associated with insulin, as Chen et al. with an OR= 3.58, 95% CI 1.37–9.35 for poor prognosis, [37] or Yu et al. with a significant increase in mortality (27.2% vs 3.5%, HR 5.38, 2.75–10.54) when they compared insulin users with non-users [38]. These results were similar to ours, as we also found a higher risk of severe outcomes for insulin in monotherapy or associated with metformin respect metformin alone. The fact that insulin is the hypoglycaemic agent of choice for managing critically ill patients or that it is a third-line therapy for diabetic patients could have influenced these outcomes, as all of them might have worst prognosis [18,39].

We found a high percentage of diabetic patients not receiving treatment (31.8%) in our population and we do not know if the results would have been different analysing only antidiabetic users or only adherent patients. We are not able to rule out that the results obtained can be more associated with the level of metabolic control than to the chronic antidiabetic therapy. We have adjusted by years of evolution of the diabetes and by the metabolic control as per HbA1c.

Among other limitations of our study there is the reliability of the COVID-19 diagnoses; we included patients without a confirmed result as during the first wave of the pandemic in our setting PCR test were not always performed. This limitation has been described in other research as during the beginning of the pandemic diagnosis test for COVID-19 were not widely available, and clinical algorithms have been used to assess COVID-19 diagnosis [40]. Another limitation is that our database is a PHC database and it only records the dates of admission and diagnoses and cause of discharge, so it is necessary to consider the lack of hospital information; for instance, we cannot capture ICU admission, ventilation or treatments and interventions administered during the admission, which clearly have influence in the prognosis and outcomes of COVID-19.

Some strengths of our study include the large number of patients included, representativeness for general population, and complete socio-demographic data. We must highlight that our cohort are PHC patients, so we have estimated the risk of death and hospitalization for a different population from the only hospitalized ones that are usually studied.

5. Conclusions

We described hospital admission and mortality rates in a large cohort of diabetic patients infected with SARS-CoV-2.

Patients treated with metformin in monotherapy had lower risk of hospitalization and death in comparison to other frequent antidiabetic treatments in our setting.

With the data available, we cannot distinguish if better outcomes are related with the antidiabetic therapy or with other factors, such as metabolic control or interventions applied during the hospital

admission.
