#### **AUTHOR CONTRIBUTION STATEMENT**

L.B and V.P. acquired and processed all clinical data. V.P. and I.V. contributed to the study concept and design. All authors participated in data analysis and interpretation and critically reviewed the final version of the manuscript. L.B, V.P. and I.V. wrote the manuscript, designed the figures and had final responsibility for the decision to submit for publication. I.V. and V.P. are the guarantor of this work and, for instance, had full access to all the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis.

#### **ACKNOWLEDGEMENTS**

There was no specific funding for this article.

#### **CONFLICT OF INTEREST**

The authors declare no conflict of interest.

## 7 **RESUMEN**

8 **Introducción:** Hay pocos datos sobre el periodo postparto en la diabetes tipo 1 (DT1). El  
9 objetivo fue evaluar la relación entre la percepción alterada de la hipoglicemia (PAH) al inicio  
10 de la gestación y la lactancia (modalidad y duración) con las hipoglicemias graves (HG)  
11 postparto (HGPP).

12 **Materiales y métodos:** Estudio retrospectivo de cohortes de mujeres con DT1 seguidas durante  
13 la gestación 2012-2019. Se recogieron las HG antes y durante la gestación. Se evaluó la PAH  
14 en la primera visita obstétrica. Los datos sobre lactancia y el periodo postparto se recogieron  
15 por cuestionario e historia clínica.

16 **Resultados:** Se incluyeron 89 mujeres con DT1 con un seguimiento postparto de 19.2 [8.7-  
17 30.5] meses; 32% tenían PAH en la primera visita obstétrica. Al alta 74 (83%) iniciaron  
18 lactancia materna durante 8 [4.4-15] meses. Dieciocho (22%) mujeres tuvieron  $\geq 1$  HGPP. La  
19 incidencia de HG aumentó significativamente del periodo pregestacional a la gestación y el  
20 postparto (0.09, 0.15 y 0.25 episodios/paciente-año, respectivamente). La tasa de HGPP fue  
21 comparable en mujeres con lactancia materna y artificial (21.4% vs. 25%, respectivamente,  
22  $p > 0.05$ ). La puntuación en el test de Clarke en la primera visita obstétrica se asoció  
23 independientemente a HGPP (por incremento de 1 punto: OR 1.53; 95% CI, 1.06-2.21). No se

24 identificaron otros predictores de HGPP entre las variables relacionadas con la diabetes o la  
25 gestación.

26 **Conclusiones:** Las HG son frecuentes en el largo plazo postparto, independientemente del  
27 modo de lactancia. Avaluar la PAH al inicio de la gestación podría identificar aquellas con un  
28 mayor riesgo de HGPP.

## 29 **ABSTRACT**

30 **Introduction:** Information regarding the postpartum period in women with type 1 diabetes  
31 (T1D) is scarce. We aim to evaluate the relation of impaired awareness of hypoglycaemia  
32 (IAH) in early pregnancy and breastfeeding status (either its presence or duration) with  
33 postpartum severe hypoglycemia (SH).

34 **Materials and methods:** Retrospective cohort study of women with T1D followed during  
35 pregnancy between 2012-2019. Data on SH were recorded before and during pregnancy. IAH  
36 was evaluated at the first antenatal visit. Data on breastfeeding and the long-term postpartum  
37 period were collected by questionnaire and from medical records.

38 **Results:** A total of 89 women with T1D were included with a median follow-up after pregnancy  
39 of 19.2 [8.7-30.5] months. Twenty-eight (32%) women had IAH at the first antenatal visit. At  
40 discharge, 74 (83%) started breastfeeding during a median of 8 [4.4-15] months. A total of 18  
41 (22%) women experienced  $\geq 1$  SH during postpartum. The incidence of SH significantly  
42 increased from pregestational to the gestational and post-partum period (0.09, 0.15 and 0.25  
43 episodes/patient-year, respectively). Postpartum SH rates were comparable in breastfeeding  
44 and non-breastfeeding women (21.4% vs. 25%, respectively,  $p > 0.05$ ). Clarke test score at the  
45 first antenatal visit was associated with postpartum SH (for each 1-point increase: OR 1.53;

46 95% CI, 1.06-2.21) adjusted for confounders. No other diabetes and pregnancy-related  
47 variables were identified as predictors of SH in this period.

48 **Conclusions:** SH are common in the long-term postpartum period independently of  
49 breastfeeding. Assessing IAH in early pregnancy could identify those at an increased risk of  
50 SH in the postpartum period.

51 **Keywords:** Severe hypoglycemia, impaired hypoglycemia awareness, postpartum, type 1  
52 diabetes, breastfeeding

## 53 1. INTRODUCTION

54 In women with type 1 diabetes (T1D), strict glycaemic control during pregnancy is paramount  
55 to improve maternal and fetal adverse pregnancy outcomes<sup>1</sup>. Glycaemic targets near  
56 normoglycemia are recommended during pregnancy<sup>2,3</sup>. Consequently, many women  
57 experience severe hypoglycaemia (SH) during pregnancy<sup>4</sup>, especially those with a history of  
58 SH or impaired awareness of hypoglycaemia (IAH)<sup>5</sup>. Nevertheless, data on SH on the  
59 postpartum period are scarce.

60 Strict glycaemic control as well as diabetes duration are risk factors for IAH in T1D. IAH leads  
61 to an increased risk of SH and its morbidity<sup>6</sup>. Pregnant women with T1D are at increased risk  
62 for IAH, especially during early pregnancy. Also, IAH has been recently identified as a new  
63 risk factor for adverse pregnancy outcomes<sup>7</sup>.

64 Women with T1D also face extra challenges after childbirth because they have a double role:  
65 caring for the newborn and managing their diabetes. Breastfeeding could add an extra challenge  
66 on daily diabetes routines in the transition to motherhood.<sup>8</sup> Immediately after delivery, insulin  
67 requirements decline to about 30-50% of the pre-pregnancy dose due to lack of placental

68 hormone influence. Together with a net increased energy demand of 500 kcal/day related to  
69 breastfeeding, insulin must be adjusted carefully to avoid SH.<sup>9,10</sup>

70 Breastfeeding initiation rates in women with T1D compared to the general population are  
71 discrepant across the literature<sup>11-14</sup>, nonetheless, most suggest that breastfeeding duration is  
72 shorter in women with T1D<sup>11-15</sup> largely explained by obstetric and sociodemographic variables  
73 <sup>11,12</sup>. Long-term breastfeeding has also been associated to metabolic control and breastfeeding-  
74 related variables like pre-birth intention to breastfeed, early breastfeeding, number of feedings  
75 in the first 24 hours and breastfeeding at discharge <sup>15-17</sup>. Glycaemic patterns of women  
76 breastfeeding and the impact of breastfeeding on glycemia, particularly in hypoglycaemia, have  
77 been insufficiently described. Likewise, whether breastfeeding increases risk of SH remains a  
78 matter of debate<sup>8,18</sup>.

79 Few studies have evaluated metabolic control in the postpartum period, mostly were performed  
80 in the first weeks postpartum ranging up to 4-6 months, with contradictory findings. Some  
81 reported similar incidence of hypoglycaemia and lower glucose variability on the first 6 months  
82 <sup>19-21</sup>, while another small study (12 breastfeeding women followed for 8 weeks) described a  
83 higher rate of non-severe hypoglycaemia episodes in breastfeeding women at 2 weeks  
84 postpartum <sup>22</sup>. SH have only been evaluated in two studies: one study identified 16 SH episodes  
85 in 11% of breastfeeding women at 4 months postpartum, being this rate similar in women who  
86 were artificially feeding; in another study, SH was reported by one (3%) mother and one (3%)  
87 control woman at 6 months post-partum. <sup>16,20</sup> The role of IAH in the incidence of postpartum  
88 SH has not been previously studied.

89 Against this background, our aim was to describe the metabolic changes on the postpartum  
90 period, during a longer time frame compared to previous studies, focusing on SH. Specifically,

91 we aim to identify the relation of IAH in early pregnancy and breastfeeding status (either its  
92 presence or duration) with postpartum SH.

## 93 **2. MATERIAL AND METHODS**

### 94 **2.1 Study design**

95 This is a retrospective, single-centre, observational cohort study of women with T1D followed  
96 during their pregnancy at a reference diabetes and pregnancy unit in a tertiary university  
97 hospital in Spain from 2012 to 2019. The study protocol was conducted according to the  
98 principles of the Declaration of Helsinki and approved by the institution's Ethics Committee.

99 All participants provided written informed consent.

100 During pregnancy, patients were followed every 1 to 3 weeks in joint visits with the  
101 endocrinologist and obstetrician until delivery. Insulin dose was reduced 50% after delivery  
102 and patients were visited again at 6 weeks postpartum. Afterwards, patients resumed follow-  
103 up with their reference endocrinologist at 3-4 months postpartum. Patients were followed  
104 according to the recommendations of the Guidelines of the Spanish Group of Diabetes and  
105 Pregnancy. HbA<sub>1c</sub> goals during pregnancy were <6.5%<sup>2</sup>.

### 106 **2.2 Data collection**

107 Demographic and anthropometrical (weight and body mass index [BMI]) data, smoking status  
108 and clinical characteristics of patients, as well as type of insulin treatment and insulin doses  
109 were collected prepregnancy (last visit before the day of the last menstrual period), at the first  
110 antenatal visit and during the pregnancy follow-up visits. Data on other comorbidities like  
111 hypertension (defined as taking antihypertensive treatment or repeated systolic blood pressure  
112  $\geq 140$  mmHg and/or diastolic blood pressure  $\geq 90$  mmHg) and dyslipidemia (defined as taking  
113 lipid-lowering drugs or LDL-cholesterol  $>160$  mg/dL) were also reported. Microvascular

114 complications were screened at the first visit: Diabetic retinopathy was defined by fundus oculi  
115 performed by a specialized ophthalmologist, diabetic nephropathy was considered if urinary  
116 albumin excretion was  $\geq 30$  mg/g confirmed on at least two out of three consecutive  
117 determinations and diabetic neuropathy when symptoms were present. Macrovascular  
118 complications were defined as a history of ischemic heart disease, ischemic stroke, transient  
119 ischemic attack (TIA) or peripheral artery disease. Glycaemic control was assessed through  
120 HbA<sub>1c</sub> values (National Glycohemoglobin Standardization Program Diabetes Control and  
121 Complication Trial (DCCT) Tosoh G8 Automated high- performance liquid chromatography;  
122 Tosoh Bioscience Inc, South San Francisco, California; normal range 4.0%- 6.0% [20- 42  
123 mmol/mol]) prior to conception (<3 months) and at each trimester during pregnancy: in the 8-  
124 10<sup>th</sup> weeks (1<sup>st</sup> trimester), 22-24<sup>th</sup> weeks (2<sup>nd</sup> trimester) and 32-34 weeks (3<sup>rd</sup> trimester).  
125 Postpartum HbA<sub>1c</sub> was the HbA<sub>1c</sub> obtained closest to the postpartum evaluation date at 17.9  
126 (9.3-28) months postpartum.

127 Women received structured education and special dietary advice on carbohydrate intake and  
128 energy intake during pregnancy.

### 2.3 Pregnancy outcomes

130 The maternal and neonatal outcomes evaluated were primary caesarean delivery, induced or  
131 dystocic deliveries, gestational hypertensive disease (including gestational hypertension and  
132 preeclampsia), large for gestational age defined as birth weight above the 90th centile for  
133 gestational age, small for gestational age (SGA) defined as birth weight below the 10th centile  
134 for gestational age, macrosomia defined as neonatal weight at or above 4000 g, prematurity  
135 (delivery before 37.0 week), severe prematurity (delivery before 34.0 week), and neonatal  
136 severe adverse outcomes (defined as any of the following: neonatal hypoglycemia [defined as  
137 plasma glucose levels of <45 mg/dl in the first 24 hours of life and <50 mg/dl thereafter],

138 obstetric trauma, neonatal hyperbilirubinemia, neonatal respiratory distress [clinical diagnosis  
139 by the neonatologist], neonatal intensive care unit admission [for treatment or observation] or  
140 perinatal death). Gestational age was defined as weeks completed based on the earliest  
141 ultrasound assessment.

## 142 **2.4 Postpartum period**

143 Data on breastfeeding (BF) initiation was collected from the obstetrics discharge documents.  
144 Specific data on the postpartum period was collected retrospectively through a questionnaire  
145 sent by email to the patients at the moment of data collection. It included questions on  
146 breastfeeding status, kind of breastfeeding (exclusive or combined), duration and reasons  
147 leading to breastfeeding discontinuation or non-initiation. It also included questions on  
148 glycaemic control during the long-term postpartum period, like a record of SH episodes,  
149 weight, insulin doses and type of insulin treatment, data complemented from clinical records.

## 150 **2.5 Hypoglycaemia evaluation**

151 SH were defined as hypoglycaemia requiring assistance from a third party. The validated  
152 Spanish version of the Clarke test was used to evaluate hypoglycaemia awareness<sup>23</sup>. A score  
153 equal or above three points was considered as IAH<sup>24,25</sup>. The Clarke test score and the number  
154 of SH episodes in the previous 2 years were registered in the first antenatal visit. SH events  
155 during pregnancy were registered prospectively at every visit. Information on SH in the  
156 postpartum period was obtained retrospectively through questionnaire.

## 157 **2.6 Statistical analyses**

158 Results are presented as **mean (standard deviation [SD])** in normal distribution, median  
159 [interquartile range (IQR)] in non- normal distribution or percentages. Normal distribution was  
160 tested for each variable using the Kolmogorov test.

161 Comparisons between groups (BF *vs.* non-BF, SH *vs.* non-SH) were performed using the  
162 Student t test for normally distributed variables or the Mann- Whitney U test for non- normally  
163 distributed variables. The McNemar test was used for paired categorical variables. Proportions  
164 were compared using a Pearson's chi- square or Fisher exact test as appropriate.

165 Logistic regression models were performed to estimate the odds ratio (OR) of (1) breastfeeding  
166 at discharge and (2) postpartum SH. The first model included pre-gestational HbA<sub>1c</sub> and BMI,  
167 age, diabetes duration, IAH and gestational SH. The second model included Clarke test score,  
168 pregnancy SH, diabetes duration, continuous subcutaneous insulin infusion (CSII) therapy,  
169 pre-gestational HbA<sub>1c</sub> and pre-gestational BMI.

170 Furthermore, the cohort was divided according to breastfeeding duration (non-BF, BF <6 or  
171 ≥6 months). For this analysis, only women who at 6 months post-partum either had completed  
172 or were still breastfeeding were included.

173 The significance level was defined as a p-value <0.05. All statistical calculations were  
174 performed using the IBM SPSS Statistics 22.0 (SPSS Inc.; Chicago, IL, USA).

### 175 **3. RESULTS**

#### 176 **3.1 Participants' characteristics**

177 A total of 89 singleton pregnancies were included in the study. Data on the postpartum period,  
178 including postpartum SH was available for 82 patients.

179 Women had a mean age of 35.3 (4.1) years and a diabetes duration of 18.6 (9) years. One third  
180 (28 [32.2%]) had IAH at the beginning of pregnancy (evaluated in the first antenatal visit at  
181 7.9 (6.9-8.5) weeks of gestation), 30 (33.7%) were using CSII and 10 (11.2%) were using  
182 continuous glucose monitoring (CGM): 6 (6.7%) were using i-MCG and 4 (4.5%), rt-MCG

183 within the context of sensor-augmented pump (SAP) systems. All women were on insulin  
184 analogs. They were on the following basal insulins: 83.3% glargine U-100, 8.3% glargine U-  
185 300, 6.3% detemir and 2.1% degludec; and prandrial insulins: 32% lispro, 66% aspart and 2%  
186 glulisine. Regarding women using CSII, 58% were on lispro and 42%, aspart. Baseline data of  
187 women included are shown in table 1.

188 Questionnaire information was obtained for 71 (79.8%) pregnancies at 19.2 [8.7-30.5] months  
189 postpartum. No differences in birth weight, gestational age, type of delivery or obstetric  
190 complications were seen between responders and non-responders to the questionnaire.

### 191 3.2 Breastfeeding characteristics

192 A total of 74 (83.1%) women were breastfeeding at discharge, with a median duration of 8  
193 [4.4-15] months. At the moment of data collection (19.2 [8.7-30.5] months postpartum), 25  
194 (33.8%) women were still breastfeeding (median duration of breastfeeding 12 [5-23] months).  
195 Most patients (57 [95%]) breastfed on demand, while only 3 (5%) did so on a fix timetable  
196 basis. Reasons for non-initiation of breastfeeding were: women's preference (n=4, 26.7%),  
197 maternal illness (n=2, 13.3%), neonatal illness (n=1, 6.7%), hypoglycaemia (n=1, 6.7%),  
198 unknown (n=7, 46.7%).

199 Compared to the non-BF group, women breastfeeding at discharge had a lower pre-pregnancy  
200 HbA<sub>1c</sub>, a lower HbA<sub>1c</sub> in the first trimester and a lower HbA<sub>1c</sub> in the long-term postpartum  
201 period (p<0.05 for all comparisons). No other differences on metabolic control during  
202 pregnancy or the postpartum period were observed (Table 2). Regarding obstetric and neonatal  
203 outcomes, the BF-group had higher birth weight (3391.6 [491.4] g vs. 2988.9 [756.8] g;  
204 p=0.010), but this was not significant after adjustment for gestational age. No other differences

1  
2  
3 205 regarding pregnancy outcomes were observed (data not shown). No predictors of breastfeeding  
4  
5 206 at discharge were identified in the logistic regression model.

6  
7 207 Lastly, the cohort was divided according to breastfeeding duration (Table 3). No significant  
8  
9 208 differences on glycaemic control were found between women breastfeeding for <6 or ≥6  
10  
11 209 months. Yet, women who did not initiate or stopped breastfeeding before 6 months more  
12  
13 210 frequently reported a medically-related cause than those breastfeeding for ≥6 months.

### 14 15 16 211 **3.3 Postpartum severe hypoglycaemia**

17  
18  
19 212 A total of 35 SH episodes were recorded, 18 (22%) women experienced one or more SH during  
20  
21 213 the long-term postpartum period (data obtained at 19.2 [8.7-30.5] months postpartum) with an  
22  
23 214 overall incidence of 0.25 episodes/patient-year. This incidence was significantly higher than  
24  
25 215 the reported in the pregestational and gestational period in the same cohort (0.09  
26  
27 216 episodes/patient-year and 0.15 episodes/patient-year, respectively).

28  
29  
30 217 Compared to women who did not suffer SH on the postpartum period, women with SH had  
31  
32 218 higher pre-pregnancy HbA<sub>1c</sub> levels, higher Clarke test score in the first antenatal visit and  
33  
34 219 higher prevalence of pre-pregnancy and pregnancy SH. No differences in metabolic control  
35  
36 220 during gestation and the postpartum period were observed (Table 4).

37  
38  
39 221 Interestingly, among women who at 6 months post-partum either had completed or were still  
40  
41 222 breastfeeding, those who suffered SH episodes were more frequently still breastfeeding at the  
42  
43 223 time of postpartum evaluation (at 19.2 [8.7-30.5] months postpartum): 60% compared to  
44  
45 224 22.5%, p=0.021.

46  
47  
48 225 With respect to pregnancy outcomes, women with postpartum SH had more frequently SGA  
49  
50 226 offspring (n=2 [11.1%] vs. n=0, p=0.046) and a higher prevalence of gestational hypertensive

227 disease (33.3% vs. 12.5% p=0.038) compared to the non-SH group. No other differences were  
228 observed (Table 4).

229 After adjustment for pregnancy SH, diabetes duration, CSII therapy, pre-gestational HbA<sub>1c</sub> and  
230 pre-gestational BMI, the Clarke test score at the first antenatal visit remained independently  
231 associated with postpartum SH (for each 1-point increase: OR 1.53; 95% CI, 1.06-2.21,  
232 p=0.024).

#### 233 4. DISCUSSION

234 In our cohort of pregnant women with T1D, both a high breastfeeding initiation rate and a long  
235 duration of breastfeeding were observed. The incidence of SH increased significantly in the  
236 long-term postpartum period compared to before and during pregnancy, although no  
237 differences were found according to breastfeeding status. Interestingly, this is the first study to  
238 identify IAH in early pregnancy as a risk factor of SH in the postpartum period in women with  
239 T1D.

240 Exclusive breastfeeding is recommended for at least 4-5 months for women with diabetes as it  
241 provides many short and long-term benefits for mothers and infants, for instance reducing  
242 childhood obesity, maternal body weight and protecting mothers from cardiovascular disease  
243 <sup>18,26</sup>. In our cohort of women with T1D, breastfeeding rates at discharge were 83.1%, slightly  
244 higher than the general population rate in our country (77%)<sup>27</sup>. Comparative rates of  
245 breastfeeding initiation in women with T1D are discrepant<sup>11,12,14</sup>. Still, most studies suggest  
246 that breastfeeding duration is shorter in women with T1D<sup>11,15</sup>, largely explained by more  
247 frequent caesarean sections, earlier delivery and lower age and education<sup>11,12</sup>. Long-term  
248 breastfeeding is also positively related to lower pre-pregnancy HbA<sub>1c</sub> and BMI, previous  
249 breastfeeding experience and early initiation of breastfeeding<sup>15,16</sup>.

250 In our study, women breastfeeding at discharge had a lower HbA<sub>1c</sub> before pregnancy, in the  
1  
2 251 first trimester and on the long-term postpartum period. Nevertheless, when adjusted for  
3  
4  
5 252 covariates, neither HbA<sub>1c</sub> at any time nor other diabetes-related variables predicted  
6  
7 253 breastfeeding at discharge in our cohort. This is with accordance to a previous study, which  
8  
9  
10 254 identified lower pre-pregnancy HbA<sub>1c</sub> with long-term breastfeeding in T1D<sup>16</sup>. Our findings are  
11  
12 255 consistent with available evidence that variables unrelated to diabetes are the main  
13  
14 256 determinants of breastfeeding initiation and duration in women with T1D<sup>14-16,28</sup>. Still, a  
15  
16  
17 257 significantly better glycaemic control before, during and after pregnancy is observed in women  
18  
19 258 who breastfeed. It would seem that breastfeeding identifies a group of women with better  
20  
21  
22 259 diabetes management. A possible explanation is that women who are more aware of the  
23  
24 260 importance of glycaemic control are also more conscious of breastfeeding benefits.

261 An interesting finding in our study was that medically-related causes were more frequently  
27  
28  
29  
30 262 reported as the cause of non-initiation or cessation of breastfeeding by women not  
31  
32 263 breastfeeding at discharge or who stopped <6 months compared to those weaning after 6  
33  
34  
35 264 months, despite no statistical differences were detected in adverse maternal or neonatal  
36  
37 265 outcomes according to breastfeeding status. Previous studies have identified high risk  
38  
39  
40 266 pregnancies, assisted and preterm deliveries, more frequent caesarean sections and longer  
41  
42 267 hospital stays as negative predictive factors of breastfeeding initiation and duration in women  
43  
44 268 with diabetes.<sup>12,18</sup>

45  
46  
47  
48 269 In this study, we identified a higher incidence of SH in the long-term postpartum period  
49  
50 270 compared to the gestational and pregestational periods: SH incidence increased nearly 2-fold  
51  
52 271 and 3-fold, respectively. Nevertheless, no relation to breastfeeding status was found in our  
53  
54  
55 272 cohort. Data on the incidence and risk of SH in the postpartum period is scarce, contradictory  
56  
57  
58 273 and limited to a short period of time after delivery. A recent study described that around two-

274 thirds of the mothers with T1D self-reported more unstable blood glucose and a quarter had  
1  
2 275 experienced hypoglycemic episodes at 2 and 6 months after delivery. Additionally, a weak  
3  
4  
5 276 association was found between lower general well-being and more unstable blood glucose at 2  
6  
7 277 months<sup>8</sup>. Another short study suggested a higher rate of hypoglycaemic episodes, particularly  
8  
9  
10 278 overnight and fasting, within 2 weeks postpartum in 12 breastfeeding women compared to the  
11  
12 279 non-breastfeeding group.<sup>22</sup> On the other hand, a study showed that despite an acute reduction  
13  
14 280 in maternal glucose was observed after suckling, this was insufficient to cause hypoglycaemia  
15  
16  
17 281 in most episodes. A lower glucose variability and a similar incidence of hypoglycaemia was  
18  
19 282 observed in breastfeeding women compared to women who artificially fed.<sup>19</sup> In another study,  
20  
21  
22 283 self-reported hypoglycaemic episodes were comparable in both breastfeeding and artificially  
23  
24 284 feeding women during the first 2 months postpartum despite lower mean glucose levels during  
25  
26  
27 285 the first week postpartum in the breastfeeding group.<sup>21</sup> None of these studies evaluated SH  
28  
29 286 episodes or IAH. Another study showed mild and severe hypoglycaemia to be comparable  
30  
31  
32 287 between women breastfeeding and artificially feeding at 4 months postpartum.<sup>16</sup> Finally, a  
33  
34 288 recent study using CGM at 1, 2 and 6 months postpartum concluded that time in hypoglycaemia  
35  
36 289 after breastfeeding at night was low and did not differ from those who artificially fed.  
37  
38  
39 290 Furthermore, breastfeeding mothers spent a higher proportion of the night-time in target range.  
40  
41 291 The SH rates were low and comparable across groups.<sup>20</sup>

42  
43  
44 292 Our results contribute to the evidence that SH risk in the postpartum period is not driven by  
45  
46  
47 293 breastfeeding at discharge. Indeed, SH in this period was related to higher Clarke test score at  
48  
49  
50 294 the first antenatal visit in our cohort. No previous studies have evaluated the role of IAH on  
51  
52 295 postpartum SH. Only one previous study, performed in the first 4 weeks postpartum and with  
53  
54 296 only 6 women completing the study, showed that several episodes of asymptomatic  
55  
56  
57 297 hypoglycaemia were detected through CGM, but conclusions could not be reached given the

298 small sample size.<sup>29</sup>. Our group has previously described that a pre-pregnancy care program  
299 improves glycaemic control and glycaemic variability without increasing SH events<sup>24,30</sup>. Thus,  
300 these findings underscore the importance of close follow-up to tackle metabolic control and  
301 hypoglycaemia awareness starting before pregnancy.

302 Importantly, in our study, SH occurred despite following the recommendation of 50% decrease  
303 in insulin dose after pregnancy as recommended by current guidelines<sup>2,3,31</sup>. Our data suggest  
304 that further decreases in insulin doses after delivery could be necessary, especially in patients  
305 at risk of SH. This is in line with recent studies that reveal that insulin requirements remain up  
306 to 21% lower than before pregnancy during the first four months postpartum<sup>10</sup>. Thus, an  
307 appropriate adjustment of insulin dose and carbohydrate intake is essential to prevent SH  
308 during breastfeeding. Various factors could explain the lower insulin requirements in the first  
309 4 months postpartum. First, independently of feeding modality, the effect of the placental  
310 hormones disappears in the immediate postpartum period, which results in a sharp decrease of  
311 insulin requirements. Secondly, exclusive breastfeeding is associated with an extra energy  
312 expenditure of 450-500 kcal/day, which is subsequently reduced when complementary feeding  
313 is started. Finally, other factors such as changes in the mother's sleep pattern could play a role.  
314 Altogether leads to decreased insulin requirements that should be acknowledged when planning  
315 the treatment adjustments after delivery.

316 In our study, 19 months after, delivery women were close to pre-pregnancy weight and insulin  
317 dose, regardless of breastfeeding status. This is in line with data at 12 months postpartum<sup>10</sup>. A  
318 qualitative study showed that women with T1D have an insufficient linkage between health  
319 care during maternity and postpartum child and diabetes care despite being in a greater need  
320 for support during this period<sup>15</sup>. Altogether points out that a closer follow-up in the first weeks  
321 and months postpartum should be pursued in the care of women with T1D. It is vital to increase

322 diabetes professionals' knowledge and awareness on the singularity of the postpartum period  
323 in terms of changes in metabolic control, especially on the high risk of SH, in order to offer a  
324 more detailed follow-up, develop specific educational interventions and improve the linkage  
325 between pregnancy and usual diabetes care.

326 Interestingly, we described a higher prevalence of gestational hypertensive disease and SGA  
327 offspring in women with postpartum SH. Women at risk of SH in the postpartum period were  
328 those with a pathological Clarke test in the first antenatal visit. Previous data of our group have  
329 shown that pregnant women with IAH had a more atherogenic lipidic profile during pregnancy  
330 and this was in turn associated with an increased risk of preeclampsia<sup>25</sup>. Our hypothesis is that  
331 the low-grade inflammation could promote an insulin-resistance state. On the other hand, the  
332 small number of SGA (n=2) precludes reaching firm conclusions and should be confirmed in  
333 a larger cohort.

334 The main strengths of our study are: First, it was developed in a single center, a reference  
335 diabetes and pregnancy unit with a homogeneous protocol and follow-up. Second, to our  
336 knowledge, this is the first study with a long-term postpartum follow-up (almost 2 years).  
337 Third, Clarke test was prospectively collected to all pregnant women in the first antenatal visit,  
338 minimizing memory bias. In addition, Clarke questionnaire is a safe, easy and quick test to  
339 identify IAH and it has been validated in several previous studies.<sup>7,32,33</sup> Nevertheless, our study  
340 has also some limitations. The relatively small sample size could preclude the detection of  
341 differences in infrequent outcomes. Still, studies on the postpartum have shown a difficulty in  
342 recruiting and retaining participants<sup>29</sup>. Moreover, although hypoglycemia awareness was only  
343 assessed at the first obstetric visit and could lead to bias, no changes in IAH during pregnancy  
344 have been observed previously<sup>5</sup>. No changes in hypoglycaemia awareness were observed in  
345 the first 6 months of breastfeeding in one study, although this data was self-reported.<sup>20</sup>

346 Additionally, very few patients were using CGM as, at the time the study was performed, CGM  
347 was not integrated in routine clinical practice. Data on percentage of time in range as well as  
348 glycemic variability measures such as standard deviation or coefficient of variation are missing.  
349 Evaluation of metabolic control was only performed by HbA<sub>1c</sub> levels, but despite its limitation  
350 in pregnancy<sup>34</sup>, it is still a robust predictor of adverse pregnancy outcomes<sup>35</sup>. Given the greater  
351 use of CGM and combined systems in recent years, a better detection of non-severe  
352 hypoglycemia will probably reduce the incidence of SH in the immediate and late postpartum  
353 period. Finally, we describe a higher incidence of hypoglycaemia after delivery compared to  
354 previous studies. This can be explained by the observation of a longer period after delivery but  
355 bias because of retrospective data collection and recall bias of SH during this period cannot be  
356 excluded.

357 In conclusion, in this cohort of women with T1D, breastfeeding rates are high and SH incidence  
358 is increased after delivery irrespective of feeding modality. In the light of our findings,  
359 hypoglycaemia awareness should be routinely assessed in early pregnancy to identify women  
360 at risk of postpartum SH. Strategies in clinical practice should be developed to improve  
361 diabetes care on the transition to motherhood in women with T1D, especially a closer follow-  
362 up during the postpartum period, specific diabetes educational support and an improved and  
363 progressive linkage to resuming usual diabetes care.
