Published online: 22 August 2024	Premature termination codons (PTCs) cause ~10–20% of inherited diseases	
Check for updates	 and are a major mechanism of tumor suppressor gene inactivation in cancer. A general strategy to alleviate the effects of PTCs would be to promote translational readthrough. Nonsense suppression by small molecules has proven effective in diverse disease models, but translation into the clinic is hampered by ineffective readthrough of many PTCs. Here we directly tackle the challenge of defining drug efficacy by quantifying the readthrough of ~5,800 human pathogenic stop codons by eight drugs. We find that different drugs promote the readthrough of complementary subsets of PTCs defined by local sequence context. This allows us to build interpretable models that accurately predict drug-induced readthrough genome-wide, and we validate these models by quantifying endogenous stop codon readthrough. Accurate readthrough quantification and prediction will empower clinical trial design and the development of personalized nonsense suppression therapies. 	

Premature termination codons (PTCs) are the cause of 10%¹ to 20%² of inherited diseases and an important mechanism of tumor suppressor gene inactivation in cancer. PTCs cause the production of truncated versions of proteins, which are typically loss-of-function and sometimes gain-of-function or dominant negatives. Many, but not all, PTCs also cause the degradation of mRNA transcripts by a process called nonsense-mediated mRNA decay (NMD), strongly reducing the production of the truncated protein^{3,4}.

A general therapeutic strategy to alleviate the effects of PTCs would be to promote translational readthrough (RT) of the stop codon (Fig. 1a). Effective nonsense suppression therapy would increase the expression of full-length proteins, reduce the production of pathological protein fragments and inhibit NMD⁵.

Multiple small-molecule drugs that promote PTC-readthrough have been discovered, with diverse mechanisms of action (MOAs) promoting the recognition of stop codons by near-cognate tRNAs rather than translation termination factors⁶. For multiple disease genes, even modest readthrough can be sufficient to alleviate disease symptoms in animal models⁷⁻¹⁰.

The extent of readthrough promoted by small molecules varies extensively for different stop codons, with most drugs increasing the readthrough of UGA more effectively than UAG and UAA PTCs¹¹⁻¹³. Testing small numbers of mutations has identified sequence features that influence the readthrough of particular stops, for example, the presence of a cytosine in position +1 after the PTC¹⁴ and the presence of an adenine at position –1 (ref. 15). To date, the largest survey of drug-induced readthrough tested the compound TLN468 on 40 variants¹⁶.

Here we deploy a deep mutational scanning (DMS) approach to generate much richer datasets quantifying nonsense suppression by different drugs. We measure the readthrough of ~5,800 human disease-causing PTCs for eight different readthrough-promoting

Fig. 1 | **Quantifying readthrough of thousands of pathogenic PTCs. a**, Readthrough drugs stimulate full-length protein synthesis and decrease NMD-mediated transcript degradation. **b**, Experimental design, -5,800 nonsense variants in human genetic diseases and cancer were retrieved from ClinVar, TCGA and MSK-IMPACT datasets, cloned in a readthrough reporter, integrated into the genome of HEK293T_LP human cell line and treated with eight readthrough compounds. A readthrough efficiency value was obtained for each variant–drug pair. **c**, Sort-sequencing overview. Each cell integrates one copy of one variant, cells are sorted based on mCherry fluorescence (*x*-axis), bins are sequenced and readthrough percentages are calculated from the mCherry distribution of reads of each variant normalized to the distribution of a no-nonsense variant. **d**, Deep mutational scanning (DMS) versus individual measurements Pearson's correlation (*r* = 0.95), where 15 variants spanning the whole readthrough

compounds (henceforth referred to as drugs). We find that the drugs vary substantially in their efficacy and also in the identity of the PTCs that they most effectively promote readthrough. We identify multiple local sequence determinants that predict PTC-readthrough efficacy and show that these determinants differ across drugs. Using these sequence determinants, we are able to build models that predict readthrough efficacy by the best-performing drugs with very good performance genome-wide ($r^2 = 0.83$). We make these models available as a resource to allow these drugs to be profiled for all possible PTCs in the human genome. Our data and models suggest that the design of clinical trials of nonsense suppression therapies could be improved by using patient–drug combinations that are predicted to be effective.

correlation (and corresponding *P* values) with measurements from previous studies^{14,16,20-24} (Spearman's correlation (ρ) = 0.56, 0.93, 0.71, 0.59, 1, 0.94, from

top-left to bottom-right plots). Titles indicate the gene for which nonsense

variants were tested and the drug used to stimulate readthrough. The bottomright plot does not show DMS estimates, but measurements of individual

variants also tested in refs. 23,24, which were used to validate the readthrough

illustrating how differences in the assay, conditions and reporter influence the

reporter. Note that the readthrough scales differ across some of the studies,

To quantify drug-induced readthrough of diverse PTCs, we constructed a library containing 3,498 PTCs that cause Mendelian diseases reported in ClinVar¹, 2,372 recurrent somatic PTCs in cancer genes (721 from The Cancer Genome Atlas (TCGA)¹⁷ plus 1,651 from MSK-IMPACT¹⁸) and a *TP53* control no-nonsense variant (n = 5,871; Fig. 1b; Methods). We cloned each PTC with 144 nucleotides (nts) of surrounding sequence context into a dual fluorescent protein reporter, where an upstream green fluorescent protein (EGFP) controls for variable expression and readthrough causes expression of a downstream mCherry protein, and performed single-copy genomic integration into HEK293T landing pad (LP) cell line¹⁹. We combined fluorescence sorting and Illumina

sequencing to obtain readthrough efficiencies (Fig. 1c and Extended Data Fig. 1a), which were highly correlated across replicates (Extended Data Fig. 1b), with individual measurements of 15 variants spanning the full dynamic range of the assay in HEK293T_LP cells (r = 0.95, $\rho = 0.86$; up to the measurement saturation limit of -6%; Fig. 1d, Extended Data Fig. 1h, Supplementary Table 1 and Supplementary Note 1) and in two other cell lines (MCF7 and HeLa; Fig. 1e). Readthrough is highly correlated across variants in the three cell types (r = 0.94-0.99), but absolute readthrough levels are about twofold lower in HeLa cells. Our measurements also correlate very well with quantifications performed in other laboratories comprising varied genes and drugs^{14,16,20-24} (Fig. 1f).

Readthrough varies extensively across drugs and PTCs

We tested four to six concentrations for 20 drugs reported to induce readthrough, of which eight induced reproducible readthrough in our assay (Extended Data Fig. 1c, d and Supplementary Table 2; Methods). We quantified the readthrough of the library in untreated conditions and under the effect of the following eight drugs: CC90009 (refs. 25,26), clitocine²⁷, 2,6-diaminopurine (DAP)¹², gentamicin^{28,29}, G418 (refs. 28,29), SJ6986 (ref. 25), SRI-41315 (refs. 30,31; henceforth: SRI) and 5-fluorouridine (FUr)8, which comprise different classes of small molecules spanning different MOAs (Fig. 1b, Methods). Considering all PTCs in the library, the median readthrough varied across drugs from 0.08% (gentamicin) to 1.32% (SJ6986; Supplementary Table 3). However, each drug promoted a stronger readthrough of a subset of PTCs, with the median readthrough of the top 10% of variants varying from 0.51% (gentamicin) to 4.28% (DAP). Readthrough distributions were unimodal with a long upper tail for seven drugs, whereas clitocine treatment resulted in a bimodal distribution (Fig. 2a and Extended Data Fig. 1i). In the absence of drugs, only a very small number of PTCs (n = 17) gave >1% readthrough. Additionally, by quantifying readthrough for three SJ6986 concentrations (0.5 μ M, 5 μ M and 20 μ M), we observed that sequence effects are preserved across drug concentrations (Extended Data Fig. 2k, l and Supplementary Note 2).

The readthrough profiles of the different drugs are, in most cases, only moderately correlated (Fig. 2b and Extended Data Fig. 1e). One exception is SRI and SJ6986, which both inhibit eRF1/eRF3 (refs. 25,30) and induce readthrough of a highly correlated set of PTCs (r = 0.93; Fig. 2b and Supplementary Note 3). The effects of other drugs are much more distinct. Clitocine and SRI, for example, both elicit high readthrough of many PTCs, but their effects are only weakly correlated (r = 0.39, in comparison to the inter-replicate correlations of r = 0.94 and r = 0.96 for the two drugs). Hierarchical clustering of the readthrough profiles of all 5,837 PTCs identifies sets of PTCs with strong readthrough induced by multiple drugs as well as PTCs strongly affected by only one drug (Fig. 2c).

Stop type and downstream sequence modulate readthrough

To better understand why the readthrough of particular PTCs is promoted by particular drugs, we quantified the association between readthrough and 47 sequence features for all drugs. These included the stop codon type, the adjacent downstream and upstream nucleotides (up to eight nucleotides away), several codon-related metrics and general features such as G + C content and RNA secondary structure propensity (Extended Data Fig. 1f and Supplementary Table 4).

Figure 2 shows data for one drug representative of each MOA, with the remaining drugs presented in Extended Data Fig. 2. Consistent with previous observations^{23,32,33}, drug-induced readthrough is much stronger for particular types of stop codon ($P < 2 \times 10^{-16}$, Kruskal–Wallis test). However, this varies extensively across drugs. For example, for G418 and SRI, the efficiency of readthrough is UGA>UAG>UAA, whereas for clitocine it is UGA>UAA>>UAG, and for DAP, it is UGA>UAG-UAA ($P < 1.7 \times 10^{-15}$ for all comparisons, one-sided Wilcoxon signed-rank test; Fig. 2d and Extended Data Fig. 2c). Drugs with the same direction of effect can also have different magnitudes of effects. For instance, both DAP and SRI stimulate UGA>UAG, but the fold change is different (4.65-fold and 1.64-fold, respectively).

To control for the strong effect of the stop codon types, in the following sections, we focus on UGA variants because they trigger the highest readthrough across all drugs (conclusions for UAG and UAA are similar, and all data are included in Supplementary Table 3, with main differences pointed out in the text). The three nucleotides immediately after a stop codon have been previously reported to modulate readthrough efficiency in the absence of drugs^{23,34}. Consistent with this, we see a strong effect of the downstream sequence (+1, +2 and +3 nts) on drug-induced readthrough ($P < 2 \times 10^{-16}$, Kruskal–Wallis test). However, as for stop codon preferences, how the downstream sequence modulates readthrough is drug-specific. Readthrough by all drugs is modulated by the nucleotide immediately after the stop codon (Fig. 2e and Extended Data Fig. 2d), with C consistently being the most efficient nucleotide. However, the rest of the nucleotide show distinct preferences across drugs.

Readthrough is also modulated by the +2 and +3 positions, and the effects differ across drugs (Fig. 2f and Extended Data Fig. 2a). We identified a stop codon-dependent effect of the downstream nucleotides (Fig. 2g and Extended Data Fig. 2e), indicating genetic interactions between neighboring nucleotides. A detailed analysis of nucleotide contexts can be found in Supplementary Note 4.

Upstream sequence modulates readthrough

Previous studies in bacteria³⁵, yeast^{36,37} and mammalian cells^{38,39} have shown that the codons upstream of a stop codon can also modulate readthrough under drug-free conditions. Clustering sequences in our library by the upstream codon revealed upstream preferences for each of the drugs ($P < 2 \times 10^{-16}$, Kruskal–Wallis test; Fig. 2h and Extended Data Fig. 2b). For instance, under SRI treatment, the codons encoding the amino acids P, G and I (n = 193) display low readthrough, as opposed to Y- and Q-encoding codons (n = 459), which drive high readthrough (1.8-fold in Q and Y versus P, G and I; $P < 2 \times 10^{-16}$, one-sided Wilcoxon signed-rank test; Extended Data Fig. 2f). Note that codons encoding the same amino acid might display different readthrough in a drug-specific fashion (Fig. 2i and Extended Data Fig. 2g,h).

To gain more insight into the effect of the upstream sequence, we clustered the codons by the identity of the third nucleotide (Fig. 2j and Extended Data Fig. 2i). Codons ending in A (n = 538 versus n = 1,457) tend to be the top-readthrough-promoting codons for all readthrough drugs, except for clitocine, although the effect differs across amino acids (1.1- to 1.3-fold change, adjusted $P < 1 \times 10^{-4}$ for DAP, G418, SRI, SJ6986 and CC90009). Additional analyses of nucleotide contexts can be found in Supplementary Note 4.

We found little association between readthrough and GC-content or codon bias indexes (codon adaptation index (CAI)⁴⁰, tRNA adaptation index (tAI)^{41,42}; Methods; Extended Data Fig. 3a–c). Controlling for nucleotide sequence does suggest an additional effect of the encoded amino acid (Extended Data Fig. 2j).

Multistop variants

Our library comprised a total of 240 genomic positions with two variants representing different stop types (named 'multistop variants'). The correlation of readthrough between pairs of stop variants ranges from ~0 to almost 0.85, depending on the drug and stop types being compared (Extended Data Fig. 3d). For instance, in SRI and SJ6986, the UGA variants correlate well in readthrough efficiency with the UAA variants, but their readthrough is two times higher. For G418, UGA variants are three times more readthrough sensitive than UAA variants. Other comparisons show very different behavior across stop types (for example, UAA versus UAG for DAP and clitocine). Examples of different stop codon variants in the same genomic position under different treatments are shown in Fig. 3a. For instance, *DMD*_S622X_UGA responds efficiently to DAP, but *DMD*_S622X_UAA responds poorly.

Fig. 2 | **Sequence features explain the readthrough variability across PTCs and drugs. a**, Readthrough distributions across drugs. The number of highconfidence variants (\geq 10 reads) recovered for each treatment and for which readthrough percentages were quantified is shown. **b**, Interdrug correlation. Correlation values between the same drug represent the inter-replicate correlation. Examples of high-correlated (SRI and SJ6986) and low-correlated (SRI and clitocine) drug pairs are shown, colored by stop type. **c**, Readthrough efficiencies for all variant–drug combinations. **d**–**j**, Effect of the sequence feature (*x* axis) on readthrough efficiency (*y* axis) in HEK293T_LP cells, colored by the drug. The top and bottom sides of the box are the upper and lower quartiles, respectively. The box covers the interquartile interval, where 50% of the data are found. The horizontal line that splits the box in two is the median. Only variants where the stop codon is UGA are shown (except for **d** and **g**, where all stop codon variants are shown). The sequence features are stop codon identity (*n* = 22,342, *P* < 2 × 10⁻¹⁶, Kruskal–Wallis test; **d**), the nucleotide in

Other examples include *PTEN_*Y88X in clitocine, *IFNGR1_*S306X in DAP/G418/SRI and *APC_*S583X in DAP/SRI.

Effective readthrough drugs for pathogenic variants

The drug-specific readthrough of different variants increases the number of patients potentially treatable by a genetically informed choice of drug. Considering all 5,837 PTCs in our library, readthrough >2% can be achieved for 50.3% by using the best drug for each mutation. This is higher than for any individual drug, with >2% readthrough for 38%, 28%, 21%, 19%, 7% and 0.6% of PTCs with DAP, SJ6986, SRI, clitocine, G418 and CC90009, respectively (Fig. 3b). By applying genetically informed position +1 downstream of the PTC ($n = 10,602, P < 2 \times 10^{-16}$; e), the nucleotides in +1, +2 and +3 positions downstream of the PTC ($n = 2,589, P < 2 \times 10^{-16}$; f), same as e but stratified by stop codon (in clitocine samples U>G for UAA stops, n = 614, adjusted $P < 2 \times 10^{-16}$; U=G for UGA stops, n = 1,395, adjusted P = 0.3; one-sided Wilcoxon signed-rank test; g), the nucleotides in -1, -2 and -3 positions upstream of the PTC together with the amino acid encoded by each codon ($n = 2,589, P < 2 \times 10^{-16}$, Kruskal–Wallis test; h) and same as h but only for variants with a glutamic acid upstream of the PTC (GAA>GAG for DAP, n = 155, adjusted $P = 7 \times 10^{-11}$; GAA=GAG for clitocine, n = 158, adjusted P = 0.6; one-sided Wilcoxon signed-rank test; i). Finally, the effect of amino acids encoded by A-ending codons on readthrough efficiency across drugs, where codons ended in A display higher readthrough compared to the rest of the codons (n = 7,989, adjusted $P < 6 \times 10^{-5}$ for DAP, G418 and SRI, one-sided Wilcoxon signed-rank test). The nucleotide upstream of the PTC is colored (j).

drug selection, many variants display even higher readthrough->3% for 27% of PTCs, >4% for 11%, >5% for 3.2% and >6% for 1.6% (Fig. 3b).

However, clinical trials usually test one drug—one gene association; hence, knowing which drug maximizes readthrough across all observed PTCs of a gene is important. The highly represented genes in our library (>20 mutations, n = 33) revealed that DAP, SJ6986 and clitocine are the most efficient drugs for most genes, but their relative order is different (Extended Data Fig. 3e). As expected, it is strongly associated with the stop type prevalence in the gene. In general, clitocine emerges as the best drug for UAA-rich genes (*APC* and *BRCA2*), DAP for UGA-rich (*ATRX* and *FAT1*) and SJ6986 for UAG-rich (*MYBPC3*)

Fig. 3 | Readthrough-sensitive nonsense variants differ across drugs. a, Readthrough efficiency for 12 multistop variants across four drugs. Each multistop variant comprises two different nonsense mutations (different stop codon identities) observed in the same genomic locus. b, Percentage of variants with readthrough over different thresholds for each drug separately and when considering all eight drugs together (All_drugs). c, All pairwise overlaps of each drug's top 50 readthrough-sensitive variants. The number indicates how many variants overlap in the top 50 readthrough-sensitive variant sets of the two compared drugs. d, Readthrough efficiency across drugs, for 102 nonsense *TP53* mutations colored by stop codon type. The top five most recurrent nonsense

mutations in the human tumor genomes are highlighted. **e**, Our observed readthrough efficiencies of the nonsense variants tested in two clinical trials (CTs) (blue), together with the rest of the nonsense variants in the same gene tested in our assay (purple). Clinical trial identifier, drug and gene tested are specified in the titles. The top and bottom sides of the box are the lower and upper quartiles. The box covers the interquartile interval, where 50% of the data are found. The horizontal line that splits the box in two is the median. **f**, Number of variants for which each drug displays the highest readthrough efficiency across the top three genes commonly tested in clinical trials for nonsense suppression therapies, considering all variants in our dataset.

and *TSC2*). Additionally, we asked whether some genes are overall more readthrough sensitive than others. The average readthrough when pooling all drugs together is normally distributed and varies between 0.9% and 1.5% across genes (>20 mutations in our library, *n* = 33).

Readthrough of tumor suppressor and disease genes

As evidenced above, there is considerable drug-specific variability in readthrough at the variant level (Fig. 2c). Comparing the top 50 most sensitive variants for each drug shows that each drug maximizes readthrough of a different set of variants (an average of 13 variants overlap across all pairwise comparisons; Fig. 3c). Thus, the best drug to apply would strongly depend on the particular nonsense mutation causing the disease in each patient.

As an example of how different drugs promote the readthrough of different PTCs, we consider the commonly mutated tumor suppressors *TP53* and *PTEN* (Fig. 3d, Extended Data Fig. 3f and Supplementary Table 5). The five most recurrent *TP53* PTCs constitute 44% of all the *TP53* nonsense mutations in the MSK-IMPACT and TCGA datasets (102 different *TP53* nonsense mutations) and are carried by 3% of all MSK-IMPACT and TCGA patients^{17,18}. These PTCs show promising readthrough therapy potential. Readthrough of the most prevalent *TP53* nonsense mutation R213X_UGA can be substantial-4.5% with DAP and 3.6% with SRI and SJ6986. Interestingly, readthrough stimulation of *TP53*_R213X_UGA bearing mice was reported to decrease tumor growth[§]. Readthrough of the second most frequent PTC, R342X_UGA, is strong with clitocine, DAP, SRI and SJ6986 (all > 2%). Q192X_UAG, the fifth most recurrent mutation, is the only variant in this set insensitive to all treatments (readthrough < 1%). In total, readthrough >2% can be achieved by at least one drug for 43/102 PTCs in *TP53*. Considering all 102 PTCs, SJ6986 is the most effective drug for 36 PTCs, DAP for 25 PTCs, clitocine for 21 PTCs, SRI for 14 PTCs and G418 for 6 PTCs in *TP53*. Encouragingly, clitocine treatment was shown to impede tumor growth in mice bearing the Q136X_UAA mutation²⁷, which displays a 2.1% readthrough in our dataset. R196X_UGA, R213X_UGA, R306X_UGA and R342X_UGA have similar readthrough efficiencies (1.9%, 2.1%, 2.1% and 2.1%, respectively), suggesting that clitocine could also have similar therapeutic potential for these four *TP53* mutations.

For *PTEN*, the four most frequent PTCs constitute 36% of PTCs reported in MSK-IMPACT (97 different *PTEN* nonsense mutations were considered here). Of these, the two more prevalent mutations (R130X_UGA and R233X_UGA) show very similar readthrough profiles with high DAP-induced readthrough (3.4% and 3.1%) and are also effectively stimulated by SJ6986 (2.0% and 2.0%), clitocine (1.7% and 1.8%) and SRI (1.8% and 1.3%; Extended Data Fig. 3f), in line with previous

observations that these mutations drive restoration of functional *PTEN* under readthrough treatment²¹. In contrast, *PTEN* Q171X_UAG and Q245X_UAG do not respond to any of the readthrough drugs tested here (readthrough <1%). In total, readthrough >2% can be achieved for 35/97 of all the PTCs reported in *PTEN* in MSK-IMPACT with at least one drug. Considering all 97 PTCs, DAP is the most effective drug for 32 PTCs, clitocine for 31 PTCs, SJ6986 for 22 PTCs and SRI for 12 PTCs.

Residual WT protein levels that partially rescue phenotypes were also reported for mucopolysaccharidosis type I-Hurler disease (>0.5% expression of *IDUA* gene)⁷ and ataxia-telangiectasia (2–5% expression of *ATM* gene)^{43,44}. Our dataset shows that 10/10 *IDUA* mutations and 28/83*ATM* mutations display readthrough >0.5% and >2%, respectively, for at least one treatment, suggesting that patients harboring those mutations could be promising candidates for readthrough therapy (Extended Data Fig. 3g).

Genetics-informed patient stratification for clinical trials

Our data highlight the highly variable efficacy of readthrough-inducing drugs across different PTCs. However, to our knowledge, only 1 of 42 phase II–IV clinical trials using readthrough-promoting drugs⁴⁵ used the genetic context of a PTC as an inclusion criterion (ClinicalTrials. gov registration: NCT04135495; Supplementary Table 6 and Extended Data Fig. 3h). Furthermore, only five trials made the identity of patient PTCs available⁴⁶⁻⁴⁸.

We used our data to evaluate the optimal match between drugs and PTCs in two of these trials (Fig. 3e). Clinical trials NCT04140786 used gentamicin and NCT04135495 used a gentamicin derivative, ELX-02. However, our data show that effective readthrough of the PTCs present in patients included in these trials is likely to have been very limited. The average readthrough of these PTCs by gentamicin is only 0.2%. In contrast, average readthrough by clitocine and DAP would be 1.8% and 2.9%, respectively, and other PTCs in the same gene would be better choices for a gentamicin trial (Fig. 3e). In the two other trials with available patient data, the most effective drug also varies across patients' PTCs and PTCs display high-readthrough variability within each drug, too (Extended Data Fig. 3i). Patient response data shows a non-significant but positive correlation with our readthrough measurements (Supplementary Note 5).

We next considered the following three genes most frequently targeted in nonsense suppression clinical trials: *DMD, CFTR* and *APC*. Our data shows that the most effective readthrough drugs for these genes are clitocine and DAP, but that, in all three cases, a combination of drugs matched to patient PTCs would prompt the highest readthrough rates (Fig. 3f). For example, of the 95 pathogenic PTCs in *DMD*, the most effective readthrough is obtained with clitocine for 30 PTCs, DAP for 26, SJ6986 for 25, SRI for 12 and G418 and CC90009 for 1PTC each. To our knowledge, none of the best three drugs (clitocine, DAP and SJ6986) have yet been evaluated in clinical trials.

Accurate prediction of readthrough efficiency

Our extensive and quantitative dataset of drug-induced PTC readthroughs provides an opportunity to train and evaluate computational models to predict drug-induced readthrough. We focused on the six drugs that triggered readthrough >1% for >3% of PTCs and used

Fig. 4 | **Interpretable models predict readthrough efficiency from sequence context. a**, Drug-specific models cross-validated predictive performance for CC90009, clitocine, DAP, G418, SJ6986 and SRI conditions. **b**, Contribution to model performance of the eight nucleotides downstream of the PTC (by adding one at a time). The fixed predictive variables present in all models are the stop codon type and the three nucleotides upstream of the PTC. *T* test over 20 crossvalidation rounds comparing each model (column) to the previous one was used to determine significance (adjusted **P* < 0.05, adjusted ***P* < 0.01, one-sided *t* test). **c**, Pan-drug models cross-validated predictive performance–drug-agnostic (top), drug-aware but sequence × drug interaction-agnostic (middle), drug and logistic regression to train sequence-based genotype-phenotype models (Supplementary Note 6). Models for the remaining three conditions (FUr, gentamicin and untreated cells) had poor predictive performance ($r^2 = 0.37, 0.38$ and 0.02, respectively) due to the very small proportion of PTCs undergoing any notable amount of readthrough in these conditions (153, 31 and 17 PTCs with >1% readthrough, respectively; Extended Data Fig. 4a,b and Supplementary Note 6).

After model optimization (Supplementary Note 6 and Extended Data Fig. 4c-e), we found that a simple model using four sequence feature groups showed good performance across all six drugs (Fig. 4a and Supplementary Table 7). The four feature groups included are as follows: (1) stop codon type; (2) the three nucleotides downstream of the PTC and their interactions; (3) the three nucleotides upstream of the PTC and their interactions and (4) the interaction between the stop type and the three nucleotides downstream of the PTC (formula 4 in Supplementary Note 8). Increasing the downstream sequence context up to +8 nts didn't improve predictive performance for any of the drugs (Fig. 4b and formula 5 in Supplementary Note 8). The correlation between predicted and observed readthrough evaluated by ten rounds of cross-validation (90-10% training-testing split) was r² = 0.89 (clitocine), 0.87 (DAP), 0.76 (SRI), 0.76 (G418), 0.71 (SJ6986) and 0.55 (CC90009). Of note, CC90009 is the dataset with the highest technical noise ($r^2 = 0.62$ inter-replicate correlation), likely hindering model performance. Training a single model with the data from all six drugs (pan-drug model) provided poor performance ($r^2 = 0.39$) unless the drug identity was included as a predictive feature with interaction terms between the drug and the additional features ($r^2 = 0.83$ for the pan-drug model; Fig. 4c, Supplementary Table 8 and formula 6 in Supplementary Note 8). This model explains 94% of the explainable readthrough variance (maximum achievable $r^2 = 0.89$ calculated via inter-replicate correlation across all variants and drugs).

To identify features important for model performance, we removed one variable at a time and calculated the drop in cross-validated *r*² normalized to the full model *r*², showing that feature contributions quantitatively differ across drug models (Fig. 4d, Extended Data Fig. 4f and Supplementary Note 7). We also compared the model coefficients for each feature (in a simplified model without the interaction term to aid coefficient interpretability; Fig. 4e, Extended Data Fig. 4g–j, Supplementary Note 6 and Supplementary Tables 9 and 10), which allowed us to capture similarities and differences of individual sequence elements across drugs.

Readthrough prediction for all PTCs in the human genome

The accurate prediction of drug-induced readthrough by our interpretable model allows us to provide readthrough predictions for every possible PTC in every transcript of the human genome (Fig. 5a). In total, one to three nucleotide substitutions can introduce 32.7 million stop codons in the 19,061 human protein-coding transcripts (Ensembl v107 genes, hg38 assembly), and we made readthrough predictions for six drugs, available as a resource named RTDetective that can be visualized along the human genome using the UCSC browser (Fig. 5b and Extended Data Fig. 5a,b; https://doi.org/10.6084/m9.figshare.23708901).

We estimate that by using these six drugs, a readthrough of >2% can be achieved for 13 million of 32.7 million (39.6%) possible stops in

sequence × drug interaction-aware (bottom). **d**, Contribution of each sequence feature to the drug-specific models. *Y* axis shows the percentage drop in r^2 when each term is removed from the model and normalized to the full model (1 – (r^2 on term removal/ r^2 full model)). **e**, Correlation of drug-specific model coefficients (note that for the sake of coefficient interpretability, we ran the models without the interaction term stop_type × down_123 nts, which incurs only a small decrease of r^2 , ranging between 1% and 3% depending on the drug). Coefficients are colored by the model feature they belong to – stop codon type, down_123 nt and up_123 nt. Drugs displaying high correlations respond similarly to the sequence features and, consequently, trigger readthrough of similar subsets of PTCs.

the human genome, with a readthrough of >1% possible for 28.6 million stops (87.3%; Fig. 5c). The individual drugs are predicted to result in >2% readthrough for 31.4%, 21.3%, 16.2%, 11.7%, 4.3% and 0.02% of PTCs for DAP, SJ6986, SRI, clitocine, G418 and CC90009, respectively. Clitocine is a mid-intensity readthrough drug but spans UAA and UGA stops, inducing 1.5–2% readthrough for many variants but higher readthrough

for only a few. Considering all 32.7 million possible PTCs, the most effective drug in 32.8% of cases is DAP, followed by clitocine (30.5%), SJ6986 (29.5%), SRI (6%) and G418 (1.1%; Fig. 5d).

Some drug-stop codon type combinations show promising potential, as illustrated for *DMD*, *PTEN* and *TP53* (Fig. 5e). DAP stimulates readthrough >2% for almost 100% of the UGA variants across

a, Generation of the comprehensive in silico dataset with all possible nonsense mutations in human coding genes. **b**, Readthrough predictions along the coding sequence (CDS) of *TP53* for each stop codon type. Each panel represents a drug-specific readthrough prediction–DAP (top), clitocine (middle) and SRI (bottom). **c**, Percentage of variants genome-wide with readthrough over a given threshold (color legend) for each drug separately and when considering all eight drugs

together (All_drugs). **d**, Percentage of the number of variants across all possible variants in the human exome for which each drug is predicted to display the highest readthrough efficiency. **e**, Cumulative histograms showing the number of variants as a function of readthrough efficiency for the genes *DMD* (top), *PTEN* (middle) and *TP53* (bottom), stratified by stop codon type as UAA (left), UAG (center) and UGA (right).

the three genes. For UAA mutations, clitocine emerges as the best candidate (readthrough >1.5% for ~50% of PTCs). For UAG mutants, the recently reported eRF1/eRF3 inhibitors SRI-41315 and SJ6986 (refs. 25,30) show promise (across *DMD*, *PTEN* and *TP53*, readthrough > 1.5% for 33% and 25% of UAG PTCs for SJ6986 and SRI, respectively, whereas readthrough > 1.5% for <0.1% of UAG PTCs for clitocine and DAP). Thus, even for UAG variants that have been considered particularly difficult to suppress, drug-induced readthrough provides a promising therapeutic strategy, provided that the correct drugs are matched to each PTC.

Readthrough of natural termination codons

Drug-induced readthrough over natural termination codons (NTCs) has been postulated as the main cause of toxicity observed in patients⁴⁹. Notably, translation termination of NTCs differs from that of PTCs, with additional elements involved, including the proximity to Poly(A) tails⁵⁰, readthrough peptide targeting pathways⁵¹ and in-frame downstream 3'-UTR stops that together reduce the generation of readthrough peptides at NTCs. Here we focus on the contribution of local sequence context to NTC readthrough, while the additional elements listed above remain to be addressed in future work.

We leveraged our system to assess the readthrough stimulation of five high-readthrough drugs (clitocine, DAP, G418, SI6986 and SRI) over NTCs from ~18.8k human protein-coding genes, preserving the upstream and downstream (3' UTR) 66 nts, but selectively removing the in-frame stops downstream (to uniquely assess the role of the stop codon proximal sequence to NTC readthrough). Readthrough measurements were highly correlated across replicates (r = 0.88-0.99), and on average, 5 million cells were sorted (~277 cells per variant) and 17,590 high-confidence variants (≥10 reads) were recovered in each experiment (Supplementary Table 11). Distributions resembled their PTC counterparts with somewhat lower readthrough (except for SJ8986), with the largest PTC-NTC differences for DAP (1.9-fold, adjusted $P < 2 \times 10^{-16}$) and SRI (1.5-fold, adjusted $P < 2 \times 10^{-16}$) drugs (Fig. 6a). This suggests a modest readthrough-protective effect of the NTC-surrounding sequence, even after removing additional downstream stops. Artificially setting the readthrough of variants whose endogenous gene has downstream in-frame stops to 0% (assuming that readthrough over two stops is ~0%), shows a strong drop in readthrough of the NTC population (Fig. 6b).

Finally, we used the drug-induced readthrough of the NTC library as an additional test of our PTC-trained predictive models (Fig. 6c).

Fig. 6 | **Quantifying readthrough for** >17,000 natural termination codons (**NTCs**). **a**, Readthrough distributions across drugs for the PTC and NTC libraries (two-sided Wilcoxon test, *** $P < 2 \times 10^{-16}$ and n = 23,459, n = 23,096, n = 22,905, n = 22,989 for clitocine, DAP, G418 and SRI, respectively, whereas P = NS and n = 23,201 for SJ6986). The top and bottom sides of the box are the lower and upper quartiles. The box covers the interquartile interval, where 50% of the data are found. The horizontal line that splits the box in two is the median. **b**, Readthrough distributions across drugs for the PTC and NTC libraries. The threshold indicates the number of amino acids downstream of the NTC considered for the analysis. NTC variants with a 3'-UTR in-frame stop codon

more proximal than the threshold are assumed to have a readthrough of 0%. Increasing the threshold increases the number of readthrough-insensitive variants. The number of NTC high-confidence variants (≥10 reads) recovered for each treatment and for which readthrough percentages were quantified are 17,812, 17,654, 17,382, 17,661 and 17,587 for clitocine, DAP, G418, SJ6986 and SRI, respectively. **c**, Drug-specific models predictive performance on the NTC dataset using NTC-trained tenfold cross-validated models (top) or PTC-trained models (bottom). **d**, Correlation of the mean readthrough for each sequence context between PTCs and NTCs, colored by the sequence feature. NS, not significant.

Performance was good across drugs (r = 0.47-0.86) and similar to that for new models trained on the NTC data itself (r = 0.52-0.88 by tenfold cross-validation; Supplementary Table 12). Indeed, the mean readthrough for each sequence feature correlates very well in PTCs versus NTCs, supporting a similar sequence context role in both translation termination scenarios (Fig. 6d).

Discussion

We have presented here a systematic quantification of drug-induced stop codon suppression comprising >140,000 readthrough measurements in human cells made using eight drugs. Our massively parallel assay represents a substantial scaling-up of data production compared to previous studies^{14,16}, generating datasets of sufficient size to train models to accurately predict drug-induced nonsense suppression genome-wide.

Our results show that each drug only induces the readthrough of a subset of pathogenic PTCs, and our models use the sequence context to predict the readthrough specificity of each drug. This diversity of drug responses means that for any particular disease gene, there is no single drug that triggers a strong readthrough of all pathogenic PTCs. Rather, effective clinical nonsense suppression will require a panel of drugs, with the appropriate drug selected for each patient according to the identity of the PTC that they carry.

The models that we have trained are deliberately interpretable and relatively simple, and yet they explain 94% of the variance in our dataset (excluding FUr and gentamicin). It is possible that black box machine learning models may further improve predictive performance, but model interpretability both aids mechanistic understanding and is desirable for models to be used in clinical decision-making⁵².

We envisage that accurate genome-scale prediction of drug-induced readthrough will improve clinical trial design and the development of personalized nonsense suppression therapies. To date, trial designs have nearly all ignored the large variation in readthrough efficacy across PTCs⁴⁵, resulting in suboptimal matching between patient PTCs and drugs. The use of the right drugs but in the wrong patients is, in retrospect, likely to have been an important cause of trial failure.

Our general approach can be used to rapidly quantify the specificities of new nonsense suppression therapeutics, allowing their clinical efficacy to then be tested in the subset of patients in which they are likely to be most effective.

Our study has some important limitations. First, readthrough was not measured in the endogenous genomic context, and long-distance features may also affect readthrough. Second, not all readthrough translation products will be functional proteins. Third, the level of readthrough required for clinical benefit will vary across proteins and diseases. Finally, the clinical efficacy of readthrough-promoting drugs will depend on additional parameters such as pharmacokinetics, pharmacodynamics and drug toxicity. Taken together, our results show that the specificities of nonsense suppression therapies differ extensively across drugs, and these specificities can be rapidly learned using high-throughput experiments to allow accurate prediction of drug responses. Looking forward, we believe that the goal should be to develop an expanding portfolio of readthrough drugs with defined and complementary specificities such that effective and specific nonsense suppression therapy can be achieved for any pathogenic stop codon in the human genome.

Methods

Ethics and consent

The study did not require any specific ethics approval. It builds on publicly available data provided by ClinVar, TCGA and MSK-IMPACT. The patient data obtained from two clinical trials were already released.

Library design

For the PTCs library, genetic disease and cancer germline variants were retrieved (n = 3498) from the ClinVar database, where all pathogenic nonsense variants whose review status was two or more stars were included (a final filtering step was carried out to decrease the penetrance of overrepresented genes such as BRCA2). Somatic cancer variants were obtained from MSK-IMPACT and TCGA databases with at least two entries in either dataset (n = 2,372). Finally, a control no-nonsense *TP53* variant (c.541C-c.687T nucleotides from ENST00000269305 transcript) was included to use as a 100% readthrough control to normalize the expression of the PTC variants and get estimates for the percentage of WT protein expression for each variant. The 147 nt spliced-mRNA context of each nonsense variant (MANE transcript isoform) was retrieved from Ensembl (v104) to preserve a large sequence context (72 nts upstream and 72 nts downstream).

For the NTCs library, the 66 nts upstream and downstream (3' UTR) for the spliced MANE isoform of all 18,824 human proteincoding genes were retrieved from Ensembl (v104). We artificially performed 1-Hamming distance substitutions to remove all in-frame 3'-UTR stop codons (TAA->TAC, TAG, TGA->TGG) to assess the role of sequence context on readthrough without the confounding influence of tandem stops. The no-nonsense *TP53* variant (c.541C-c.687T nucleotides from ENST00000269305 transcript) was included to use as a 100% readthrough control.

No statistical methods were used to predetermine sample sizes of the libraries, but our sample sizes are 100–1,000 folds larger than those reported in previous publications^{11–14,16}.

Readthrough reporter

We designed a double fluorescent reporter plasmid (pIT092) to quantify readthrough. The plasmid encodes a single transcript that contains the open reading frames (ORFs) of EGFP, T2A (2×) and mCherry from 5'-3', respectively. The library oligo pool was cloned in-frame between the two T2A sequences. T2As allow the independent folding of the fluorescent proteins and prevent undesired effects of the variable sequence on their folding and stability. In a normal translation event, termination occurs in the PTC of the library, protecting mCherry from translation. However, if readthrough occurs, the ribosome extends elongation until the mCherry stop codon translating the mCherry protein along the way. Hence, mCherry fluorescence is proportional to readthrough efficiency, and we used it as our assay readout. EGFP is used to filter out those cells that either do not have EGFP or have unexpectedly high levels of EGFP. These cells are likely to have either aberrant cloning, out-of-frame integration, promoter mutations, promoter silencing, transcript-stability mutations, etc., and might be misleading if included in the assay. For some of the treatments, we detect a slight EGFP increase in the mCherry⁺ population, suggesting a readthrough-mediated transcript stabilization either via NMD inhibition or translation-mediated mRNA protection. In those cases, the mCherry increase (in mCherry⁺ versus mCherry⁻ populations) is higher than the EGFP increase, proving that the drugs are increasing the mCherry signal via readthrough. pIT092 is suitable for genomic integration using the HEK293T landing pad (LP) system¹⁹, which ensures that each cell integrates only one variant providing a direct genotypephenotype linkage. The vector contains BxBI-compatible attB sites that allow recombination into the genomic LP of HEK293T_LP cells. After genomic integration into the LP locus, the ORF sequence is placed right downstream of a tetracycline induction cassette, allowing its expression when doxycycline is added to the media.

Library cloning

Oligos were ordered as an oligo pool to Twist Biosciences containing the variable part (library) and two constant sequences for PCR amplification and subcloning. The oligo pool was PCR-amplified for 14 cycles using primers oIT204 and oIT340 (Supplementary Table 14). The oligo pool was cloned between the EGFP-T2A and T2A-mCherry ORFs of pIT092 using Gibson Assembly. The library was electrotransformed using Neb10 electrocompetent bacteria and grown in 100 ml overnight culture. Library complexity and representativity of the variants were estimated by plating a small amount of the transformation reaction and extrapolating the total number of transformants. Individual clones were Sanger sequenced to confirm the expected structure and diversity.

Stable cell line generation

To generate the cell lines, we used the HEK293T LP cell line generated in ref. 19 (TetBxB1BFP-iCasp-Blast Clone 12 HEK293T cells), which allows the stable single-copy integration of variants in the genome. Mutational libraries cloned into the LP compatible construct (pIT092) are cotransfected (1:1) with a BxBI expression construct (pCAG-NLS-Bxb1) into the HEK293T_LP cell line using lipofectamine 3000 according to the manufacturer's instructions in three T150 cm² flasks. This cell line has a genetically integrated tetracycline induction cassette, followed by a BxBI recombination site and a split rapalog-inducible dimerizable Casp-9. Cells were maintained in DMEM supplemented with 10% FBS tetracycline-free without antibiotics. Two days after transfection, doxycycline (2 µg ml-1; Sigma-Aldrich) was added to induce expression of the library (recombined cells) or the iCasp-9 protein (no recombination). Twenty-four hours later. 10 nM rimiducid (Selleckchem. AP1903) was added to the cells. Successful recombination frameshifts the iCasp-9 out of frame. However, nonrecombined cells express iCasp-9, which dimerizes in the presence of rimiducid and induces apoptosis. One day after rimiducid treatment, the media was changed back to DMEM + doxycycline, and cells were maintained in culture for the following 5 days to obtain a large volume of cells for downstream experiments and cryostorage.

Readthrough compounds

We tested a panel of 20 compounds reported to have readthrough activity (Supplementary Table 2), in our library-integrated HEK293T LP cells. If a drug induces readthrough, the fluorescence-activated cell sorting (FACS) profile would be different than the untreated cells; specifically, we would observe an increase in the mCherry⁺ population (Extended Data Fig. 1a). Readthrough was calculated as the (mCherry⁺ and EGFP⁺)/(EGFP⁺) cell ratio multiplied by the mean mCherry intensity of the mCherry⁺ population and normalized to the readthrough of the no-nonsense variant (Extended Data Fig. 1d). All drugs were tested at four or more different concentrations ranging along orders of magnitude, to ensure that a negative result was not due to a concentration-related problem. The 4×10^{5} library-integrated HEK293T_LP cells were seeded in six-well plates and treated with 2 µg ml⁻¹ doxy to induce the expression of the transcript, and after 24 h, the drug was added to the medium. Readthrough was measured 48 h after treatment with the BD LSRFortessa Cell Analyzer as described above. Eight drugs, namely SRI, clitocine, SJ6986, DAP, G418, gentamicin, CC90009 and FUr, were validated, whereas the remaining 12 did not trigger detectable readthrough in our system at the tested concentrations. We did toxicity titrations for the eight positive drugs (Extended Data Fig. 1c). In total, 2×10^4 cells were plated in 96-well plates, and the CellTiter-Glo Luminescent Cell Viability Assay (Promega) was used to quantify cell viability 48 h after drug or vehicle treatment using a Tecan Infinite M Plex plate reader (Tecan). For each drug, the concentration that didn't decrease cell viability by more than 25% and exhibited the highest readthrough was selected (Extended Data Fig. 1c,d). For G418, we chose a concentration that dropped cell

viability by a slightly different quantity of 30%, because the increase in readthrough was substantial, compared to the concentration that reduced viability by 25%. Also, note that very high concentrations of gentamicin and G418 were used to counteract the effect of the aminoglycoside-resistance cassette of the HEK293T_LP cells¹⁹.

The validated drugs comprise different classes of small molecules. G418 and gentamicin bind to the decoding center of the small ribosomal subunit; SRI, SJ6986 and CC90009 are eRF1/eRF3 inhibitors; DAP interferes with the activity of a tRNA-specific 2'-O-methyltransferase (FTSJ1); and clitocine and FUr are nucleotide analogs that get incorporated into the mRNA. Some were reported decades ago, and their readthrough potential is supported by extensive literature (gentamicin, G418) and tested in several clinical trials (most of them with disappointing and confusing outcomes). In contrast, others have been recently described as drugs, and little is known about their readthrough stimulatory potential.

FACS

Cells were grown on standard culture plates in tetracycline-free DMEM supplemented with 10% FBS, and without antibiotics. They were split before reaching confluency to maintain cell health. Cells were detached with trypsin, spun down and washed with PBS. For the sort-seq experiments³³, cells were treated with 2 μ g ml⁻¹doxy to induce the expression of the transcript, and after 24 h, the drug was added to the medium for 48 h more. We used high volumes of cells to ensure that each variant was represented >100 times in the cell population.

Cells were sorted on a BD Influx Cell Sorter and analyzed with BD FACS Software (1.0.0.650). Cells were gated by forward scattering area and by side scattering area to retain whole cells, forward scattering width and height to discard aggregates, and by DAPI staining to retain only recombined and alive cells. EGFP and mCherry fluorescence were excited with 488 nm and 561 nm lasers and recorded with 530/40 bandpass (BP) and 593/40 BP channels, respectively. EGFP⁺ cells were sorted based on mCherry expression into three to five populations (Extended Data Fig. 1a), depending on how stretched the library was across the mCherry axis. The top-right population in the Extended Data Fig. 1a plots represents the no-nonsense variant and was sequenced for one drug condition (gentamicin) of the natural stops library. In total, 30% of the reads in that population indeed map to the no-nonsense TP53 variant, in contrast to <0.01% in the other populations (Extended Data Fig. 1g). For most of the populations, 400k cells were sorted. However, for some minor populations representing <2% of the total population, we sorted less cells (100-200k). The percentage of cells in each bin population was used for normalization during sequencing analysis (see below). Experiments were performed in biological duplicates, and, on average, 1.6 million cells were sorted in each drug experiment (~272 cells per variant).

DNA extraction

Sorted cells were centrifuged at 1,200 rpm for 3 min, and the pellet was used to conduct genomic DNA extraction following the DNeasy Blood & Tissue Kit (Qiagen) and resuspended in 80 μ l of Milli-Q water.

Sequencing library preparation

The sequencing libraries were constructed in three consecutive PCR reactions. The first PCR intends to amplify the library fragment from the genomic DNA pool without amplifying the remaining plasmid from transfection. It uses a forward (oIT314) primer annealing in the LP outside of the recombined sequence and a reverse (oIT205) primer annealing at the 3' end of the library fragment. This ensures that plasmid DNA is not amplified because it lacks the annealing site for the forward primer. The second PCR (PCR2) was designed to insert part of the Illumina adapters and to increase the nucleotide complexity of the first sequenced bases by introducing frame-shift bases between the adapters and the sequencing region of interest. The third PCR

All genomic DNA extracted from each bin was used as a template for PCR1 and amplified using 25 pmol of primers oIT205 and oIT314. The annealing temperature was set to 66 °C, extension time to 1 min and number of cycles to 25. Because high volumes of genomic DNA inhibit PCR reactions, we aliquoted each sample in eight PCRs and ran them in 96-well plates. Excess primers were removed by adding 0.04 μ l of ExoSAP-IT (Affymetrix) per microliter of PCR1 reaction and incubated for 20 min at 37 °C followed by an inactivation for 15 min at 80 °C. Then, the PCRs of each sample were pooled together and purified using the MinElute PCR Purification Kit (Qiagen) according to the manufacturer's protocol. DNA was eluted in Milli-Q water to a volume of 20 μ l.

In total, 2 μ l of PCR1 product were used as template for PCR2, together with 25 pmol of pooled frame-shift primers (oIT_ILL_204_mix and oIT_ILL_205_mix; Supplementary Table 14). The PCR reactions were set to an annealing temperature of 66 °C, 15 s of extension time and were run for eight cycles. Excess primers were removed by adding 0.04 μ l of ExoSAP-IT (Affymetrix) per microliter of PCR1 reaction and incubated for 20 min at 37 °C followed by an inactivation for 15 min at 80 °C. The PCRs of each sample were purified using the MinElute PCR Purification Kit (Qiagen) according to the manufacturer's protocol. DNA was eluted in Milli-Q water to a volume of 10 μ l.

In total, 2 µl of PCR2 products were used as template for PCR3. In PCR3, the remaining parts of the Illumina adapters were added to the library amplicon. The forward primer (olT_GJJ_1J) was the same for all samples, while the reverse primer (olT_GJJ_2J) differed by the barcode index, to allow pooling of all samples together and demultiplexing after deep sequencing (Supplementary Table 14). Eight cycles of PCR3s were run at 62 °C of annealing temperature and 25 s of extension time. All reactions from the same sample were pooled together, and an aliquot was run on a 2% agarose gel to be quantified. After quantification, samples with different Illumina indexes that were sequenced together in the same flow cell were pooled in an equimolar ratio, run on a gel and purified using the QIAEX II Gel Extraction Kit. The purified amplicon library pools were subjected to 150-bp paired-end NextSeq 500 sequencing (Illumina) at the CRG Genomics Core Facility.

Sequencing data processing

FastQ files from paired-end sequencing of all experiments were processed with DiMSum (v.1.3; https://github.com/lehner-lab/DiMSum) to obtain the read counts for each variant. DimSum applies stringent quality filters to discard low-quality reads, reads with sequencing errors, etc., to ensure that only high-quality reads are used for downstream analysis.

The DimSum output read count tables were used to calculate readthrough estimates for each variant as follows: the read count table provides the distribution of each variant among the different sorting gates. Because gates harbored different percentages of the general population, they had to be sorted at different times to get the same number of cells in each bin, forcing us to calculate the mCherry distributions in relative numbers (formula 1 in Supplementary Note 8). The distribution of each variant is generated by calculating its proportion of reads in each sorting gate (j), with m being the total number of sorting gates. All reads of a given variant in a given sorting gate (r_i) are (1) divided by the total number of reads of that gate (R_i) yielding a normalized reads value, (2) multiplied by a fixed value (pc) corresponding to the percentage of cells of the total population that belong to that gate and (3) and multiplied by a second fixed value (fv) corresponding to the mean mCherry signal of the gate. Finally, (4) it is averaged by the total number of normalized reads across gates (N). In steps (1) and (2), we are simply calculating the percentage of reads of the total population belonging to each variant in each gate $(\frac{r_j}{R} pc_j)$. In steps (3) and (4)

we obtain a value corresponding to a normalized mean mCherry value for each variant. Then, by dividing this mCherry value of each variant by the mCherry value of the untreated no-nonsense variant (which represents the amount of WT protein in basal conditions), the readthrough percentage for each variant (RTp, percentage of WT protein expression) is calculated (formula 2 in Supplementary Note 8). The no-nonsense population does not undergo readthrough and displays the same mCherry value across treatments, as expected. However, under clitocine conditions, its mCherry signal is 1.6-fold higher, suggesting an RNA stabilization effect of clitocine. The normalization with the no-nonsense variant in the untreated condition sets all the treatments' readthrough distributions on the same scale and allows direct comparison across drugs. The EGFP⁻/mCherry⁻ population was used to calibrate the voltage of the sorting instrument across treatments and replicates. The standard deviation (s.d.) from the two replicates was used as the error measure. Readthrough percentage efficiencies for all variants and drugs are included in Supplementary Tables 3 (PTCs) and 11 (NTCs). Experiments were performed in biological duplicates, and, on average, 5,602 high-confidence variants (≥ 10 reads) were recovered in each experiment. We retained variants with \geq 10 reads. Shapiro–Wilk test was used to determine the non-normality of the sample, and accordingly, nonparametric tests (Kruskal-Wallis and Wilcoxon signed-rank tests) were used to assess significance. Note that the two clitocine replicates were sigmoidally related due to a difference in the voltage setting of the flow cytometer between experiments. A LOESS model was fit and used to predict replicate 2 based on replicate 1. This transformation yielded a linear relation between the two replicates.

Single-variant validation experiments

To validate the assay, we set out to individually measure the readthrough of 15 variants. We selected 15 variants spanning the whole dynamic range when treated with SRI plus the no-nonsense control and individually cloned and integrated them into HEK293T_LP, yielding 16 stable cell lines each expressing a different variant. In parallel, we conducted the same measurements in MCF7 and HeLa cell lines (cells were maintained in tetracycline-free DMEM supplemented with 10% FBS without antibiotics). Because the LP is unique to HEK293T cells, we used transient transfection to express the readthrough variants in MCF7 and HeLa cell lines. Constructs harboring the 16 variants were cloned out from pIT092 and cloned in a mammalian CMV-expression vector (pIT075).

HEK293T_LP were treated with 2 µg ml⁻¹ doxy, and 50 ng of pIT075 plasmids were transfected into MCF7 and HeLa with lipofectamine 3000. Twenty-four hours later, cells were treated with SRI at the same concentration than used in the DMS assay (7.5 µM). 48 h after treatment, EGFP and mCherry fluorescence were quantified using 530/40 BP and 593/40 BP channels in the BD LSRFortessa Cell Analyzer. EGFP⁺ cells were used to calculate the readthrough by multiplying the percentage of mCherry⁺ cells by its mean mCherry intensity and finally normalizing to the no-nonsense variant (formula 3 in Supplementary Note 8). We termed these readthrough values as 'readthrough *P*_{individual}' because they refer to individual measurements of readthrough percentages of each variant. Readthrough *P*_{individual} were correlated against the readthrough *P*_{DMS} estimates of the 15 variants to calculate the correlation coefficient between our DMS assay and individually measured readthrough (Supplementary Table 1).

Sequence features

We listed a large set of sequence features to test their contribution to readthrough variability. Features were chosen based on literature and preliminary results, but we also listed several features for which we had no evidence of their participation in readthrough. All features tested in the predictive models can be found in Supplementary Table 4. See Supplementary Note 6 for extended information on model design. The tAI is a measure of translational efficiency that takes into account the intracellular concentration of tRNA molecules and the efficiencies of each codon–anticodon pairing^{41,42}. The pairing affinity of each codon–anticodon is specific to each species. The human-specific tAI indexes were downloaded from the STADIUM database as of January 2023 (ref. 54). tAI for a given sequence was calculated as the mean tAI across all codons of the sequence.

CAI

The CAI is an estimate of translational efficiency based on the similarity of codon usage of one sequence with regard to the genome codon usage⁴⁰. The human codon usage table was downloaded from the Codon/Codon Pair Usage Tables project release as of January 2023 (ref. 55). CAI for a given sequence was calculated as the mean CAI across all codons of the sequence.

In silico saturation mutagenesis

We used the general drug model to perform an in silico prediction of the readthrough efficiency of all possible nonsense mutations in the human exome, resulting in 32.7×10^6 predictions for the 19,061 protein-coding transcripts (Ensembl v107 genes, hg38 assembly) for each drug. For each codon position of each protein-coding transcript, a readthrough efficiency value was estimated for each drug.

Statistics and reproducibility

Statistical tests were performed in R (v4.3.1) using RStudio (v2023. 03.0+386). Kruskal–Wallis tests were used to assess the general association of sequence features and readthrough, whereas Wilcoxon tests were used for pairwise comparisons of specific levels of the sequence features. Wilcoxon tests were either one- or two-sided, and this information is always provided in the figure legend. *P* values were adjusted using the p.adjust function in R (Benjamini–Hochberg). No statistical method was used to predetermine the sample size. Variants with <10 reads were not used for analyses, and analyses included all other variants unless explicitly indicated. No blinding or randomization was performed.

Reporting summary

Further information on research design is available in the Nature Portfolio Reporting Summary linked to this article.

Data availability

All DNA sequencing data have been deposited in the Sequence Read Archive with accessions PRJNA996618 (PTCs) and PRJNA1073909 (NTCs). The readthrough efficiency predictions have been made available through the Figshare repository at https://figshare.com/ articles/dataset/Readthrough_predictions/23708901 and via a digital object identifier (https://doi.org/10.6084/m9.figshare.23708901). All readthrough measurements are provided in Supplementary Tables 3 and 11.

The MSK-IMPACT and TCGA datasets were downloaded from cBio-Portal (https://www.cbioportal.org/) on 2 June 2021. The ClinVar dataset was downloaded from https://ftp.ncbi.nlm.nih.gov/pub/clinvar/ vcf_GRCh38/ on 3 June 2021. Source data are provided with this paper.

Code availability

Source code used to perform all analyses and to reproduce all figures in this work is available at GitHub (https://github.com/lehner-lab/ Stop_codon_readthrough) and has been archived to Zenodo (https:// zenodo.org/records/12698349)⁵⁶.

Extended Data Fig. 2 | **Sequence features explain the readthrough variability across PTCs and drugs. a**-i, Effect of the sequence feature (*x*-axis) on readthrough efficiency (*y*-axis) colored by drug. The top and bottom sides of the box are the lower and upper quartiles. The box covers the interquartile interval, where 50% of the data are found. The horizontal line that splits the box in two is the median. Only variants where the stop codon is UGA are shown (except for c and e, where all stop codon variants are shown). The sequence features are the three nucleotides downstream of the PTC (n = 10645, p < 2e-16, Kruskal–Wallis test) (a), the three nucleotides upstream of the PTC (n = 10645, p < 2e-16) (b), the stop type (n = 22227, p < 2e-16) (c), the nucleotide in position +1 downstream of the PTC (n = 10502, p < 2e-16) (d), same as d but stratified by stop codon (n = 16753) (e), the amino acid upstream of the PTC (n = 10602,

p < 2e-16) (f), variants with a glutamic acid upstream of the PTC stratified by the

codon (n = 613) (**g**), variants with an arginine upstream of the PTC stratified by the codon (n = 1040, p = 3e–6) (**h**), and the effect of amino acids encoded by A-ending codons on readthrough efficiency for FUr, gentamicin, CC90009 and SJ6986, where codons ended in A display higher readthrough efficiencies compared to the rest of the codons (n = 7902, adjusted p < 1e–3, one-sided Wilcoxon signed-rank test). The nucleotide in position +3 of the codon is denoted with colors (**i**). **j**, Mean readthrough difference between pairs of codons with Hamming distance of 1 (that is, single nucleotide difference) that encode for the same amino acid, or pairs that encode a different amino acid across drugs. *P* value of the two-sided t-test between the same amino acid and different amino acid groups is shown. **k**,**l**, Readthrough distributions (**k**) and pairwise correlations (**l**) for the three SJ6986 concentrations tested (0.5 μ M, 5 μ M and 20 μ M).

Extended Data Fig. 3 | See next page for caption.

Extended Data Fig. 3 | **Codon-related features, multistop variants and** overview of PTEN nonsense mutations and clinical trials. a-c, Correlation of tAl (**a**), CAI (**b**) and GC% (**c**) of the 5aas upstream of the PTC with readthrough efficiency for each drug. **d**, Correlation of multistop variants across drugs. Each data point belongs to a mutation in the same genomic position but with a different stop type. **e**, Drug preferences for the highly represented genes in our dataset (>20 variants, n = 33). Y-axis shows the percentage of mutations for which each drug displays the highest readthrough. **f**, Readthrough efficiency across drugs for 97 nonsense *PTEN* mutations colored by stop codon type. The top 4 most recurrent nonsense mutations in human tumors are highlighted. **g**, Percentage of *IDUA* and *ATM* mutations in our dataset displaying higher readthrough levels than the phenotypic threshold reported in refs. 7,43,44 across drugs. **h**, All past and current (n = 42) phases II–IV clinical trials testing readthrough drugs, obtained from ref. 45. **i**, Our readthrough efficiencies of the nonsense variants tested in two clinical trials (CTs) (blue), together with the rest of nonsense variants in the same gene tested in our assay (purple). Clinical trial identifier, drug (ataluren) and gene tested are specified in the titles. Many variants included in clinical trials are unresponsive to drugs, likely hindering their performance. The top and bottom sides of the box are the lower and upper quartiles. The box covers the interquartile interval, where 50% of the data are found. The horizontal line that splits the box in two is the median.

Extended Data Fig. 4 | See next page for caption.

Extended Data Fig. 4 | Predictive models overview and optimization. a, Drugspecific models cross-validated predictive performance for FUr, gentamicin and untreated conditions. **b**, Downsampling the number of readthrough variants yields decreased model performance for the high-performing drug models (Supplementary Note 6). X-axis shows the number of variants with readthrough >1% retained and used to rerun the models (gray). We used control models randomly removing the same number of variants to control for the effect of smaller training sizes in model performance (black). Models with 20, 50 and 150 variants retained intend to represent similar scenarios to untreated, gentamicin and FUr datasets. The r²s shown are the average over 10 crossvalidation rounds. **c**, Comparison of the r² values for the drug-specific models when using stop type, the three nucleotides downstream and upstream of the PTC and the interaction between stop type and three nucleotides downstream versus when using ElasticNet regularization on 47 sequence features (Extended Data Fig. 1f and Supplementary Table 4). d, Performance for three different model formulations across drugs (Supplementary Note 6): using only stop type and the three nucleotides downstream and upstream of the PTC, adding the stop type and three nucleotides upstream interaction or adding the stop type and three nucleotides downstream interaction. Only the latter consistently

improves model performance across drugs. The r²s shown are the average over 10 cross-validation rounds. e, Performance for three different model formulations across drugs: encoding the three nucleotides downstream and upstream of the PTC as nucleotide triplets (m1), encoding the upstream sequence as a nucleotide triplet and the three nucleotides downstream as three different terms (one for each position, no interaction among them, m2) and encoding the downstream sequence as a nucleotide triplet and the three nucleotides upstream as three different terms (one for each position, no interaction among them, m3). m1 consistently yields higher r² across drugs. The r²s shown are the average over 10 cross-validation rounds. f, Contribution of each sequence feature to the pandrug model. The y-axis shows the relative drop in r² when each term is removed from the model and normalized to the full model $(1 - (r^2 upon term removal/r^2 full))$ model)). g-i. Model coefficients of the following predictive models: CC90009 and clitocine (g), DAP and SJ6986 (h), G418 and SRI (i) and the down 123 nt (top) and up 123 nt (bottom) coefficients for the pan-drug model (j). Mean, 95% confidence intervals and significance (two-sided Student's t-test) of the coefficient estimates across 10 cross-validation rounds are shown. Asterisks represent an adjusted p-value < 0.01.

Extended Data Fig. 5 | **In silico PTC saturation mutagenesis. a**, Overview of the readthrough predictions along the coding sequence of *TP53* for each stop codon type. Each panel represents a drug-specific prediction: G418 (top), CC90009 (middle) and SJ6986 (bottom). **b**, Same as **a**, but drugs are represented as colors and each panel belongs to a different stop type.

Reporting Summary

Nature Portfolio wishes to improve the reproducibility of the work that we publish. This form provides structure for consistency and transparency in reporting. For further information on Nature Portfolio policies, see our <u>Editorial Policies</u> and the <u>Editorial Policy Checklist</u>.

Statistics

For	all st	atistical analyses, confirm that the following items are present in the figure legend, table legend, main text, or Methods section.
n/a	Cor	firmed
	\boxtimes	The exact sample size (n) for each experimental group/condition, given as a discrete number and unit of measurement
		A statement on whether measurements were taken from distinct samples or whether the same sample was measured repeatedly
		The statistical test(s) used AND whether they are one- or two-sided Only common tests should be described solely by name; describe more complex techniques in the Methods section.
		A description of all covariates tested
		A description of any assumptions or corrections, such as tests of normality and adjustment for multiple comparisons
	\boxtimes	A full description of the statistical parameters including central tendency (e.g. means) or other basic estimates (e.g. regression coefficient) AND variation (e.g. standard deviation) or associated estimates of uncertainty (e.g. confidence intervals)
		For null hypothesis testing, the test statistic (e.g. F, t, r) with confidence intervals, effect sizes, degrees of freedom and P value noted Give P values as exact values whenever suitable.
\ge		For Bayesian analysis, information on the choice of priors and Markov chain Monte Carlo settings
\boxtimes		For hierarchical and complex designs, identification of the appropriate level for tests and full reporting of outcomes
	\boxtimes	Estimates of effect sizes (e.g. Cohen's d, Pearson's r), indicating how they were calculated
		Our web collection on <u>statistics for biologists</u> contains articles on many of the points above.

Software and code

 Policy information about availability of computer code

 Data collection
 FastQ files from paired-end sequencing of all experiments were processed with DiMSum v1.2.9 using default settings with minor adjustments: https://github.com/lehner-lab/DiMSum. Experimental design files and command-line options required for running DiMSum on these datasets are available on GitHub (https://github.com/lehner-lab/Stop_codon_readthrough).

 Data analysis
 Source code is available at https://github.com/lehner-lab/DiMSum. Source code for all downstream analyses and to reproduce all figures described here is available at https://github.com/lehner-lab/Stop_codon_readthrough and has been archived to Zenodo (https://zenodo.org/ records/12698349). FACS data was analyzed with BD FACS (TM) Software (1.0.0.650).

For manuscripts utilizing custom algorithms or software that are central to the research but not yet described in published literature, software must be made available to editors and reviewers. We strongly encourage code deposition in a community repository (e.g. GitHub). See the Nature Portfolio guidelines for submitting code & software for further information.

Policy information about availability of data

All manuscripts must include a data availability statement. This statement should provide the following information, where applicable:

- Accession codes, unique identifiers, or web links for publicly available datasets
- A description of any restrictions on data availability
- For clinical datasets or third party data, please ensure that the statement adheres to our policy

All DNA sequencing data have been deposited in the Sequence Read Archive (SRA) with accession number PRJNA996618: http://www.ncbi.nlm.nih.gov/ bioproject/996618 (PTCs) and PRJNA1073909: http://www.ncbi.nlm.nih.gov/bioproject/1073909 (NTCs). The readthrough efficiency predictions have been made available through the Figshare repository at https://figshare.com/articles/dataset/Readthrough_predictions/23708901 and via a digital object identifier (doi:10.6084/m9.figshare.23708901). All readthrough measurements are provided in Extended Data Tables 3, 11. The MSK-IMPACT and TCGA datasets were downloaded from cBioPortal (https://www.cbioportal.org/) on 02.06.2021. The ClinVar dataset was downloaded from https://ftp.ncbi.nlm.nih.gov/pub/clinvar/vcf GRCh38/ on 03.06.2021.

Research involving human participants, their data, or biological material

Policy information about studies with human participants or human data. See also policy information about sex, gender (identity/presentation), and sexual orientation and race, ethnicity and racism.

Reporting on sex and gender	Use the terms sex (biological attribute) and gender (shaped by social and cultural circumstances) carefully in order to avoid confusing both terms. Indicate if findings apply to only one sex or gender; describe whether sex and gender were considered in study design; whether sex and/or gender was determined based on self-reporting or assigned and methods used. Provide in the source data disaggregated sex and gender data, where this information has been collected, and if consent has been obtained for sharing of individual-level data; provide overall numbers in this Reporting Summary. Please state if this information has not been collected. Report sex- and gender-based analyses where performed, justify reasons for lack of sex- and gender-based analysis.
Reporting on race, ethnicity, or other socially relevant groupings	Please specify the socially constructed or socially relevant categorization variable(s) used in your manuscript and explain why they were used. Please note that such variables should not be used as proxies for other socially constructed/relevant variables (for example, race or ethnicity should not be used as a proxy for socioeconomic status). Provide clear definitions of the relevant terms used, how they were provided (by the participants/respondents, the researchers, or third parties), and the method(s) used to classify people into the different categories (e.g. self-report, census or administrative data, social media data, etc.) Please provide details about how you controlled for confounding variables in your analyses.
Population characteristics	Describe the covariate-relevant population characteristics of the human research participants (e.g. age, genotypic information, past and current diagnosis and treatment categories). If you filled out the behavioural & social sciences study design questions and have nothing to add here, write "See above."
Recruitment	Describe how participants were recruited. Outline any potential self-selection bias or other biases that may be present and how these are likely to impact results.
Ethics oversight	Identify the organization(s) that approved the study protocol.

Note that full information on the approval of the study protocol must also be provided in the manuscript.

Field-specific reporting

Please select the one below that is the best fit for your research. If you are not sure, read the appropriate sections before making your selection.

Life sciences study design

All studies must disclose on these points even when the disclosure is negative.

Sample size	5837 variants in PTC library, 18824 in NTC library. During library construction, we used several fold larger number of cells to ensure that each variant was integrated in ~100 cells. For the PTC library, the library size (n=5837) was chosen based on a) to have a good representativity of sequence contexts around the stop (see the same nucleotide-position combination in many different variants to be able to regress out the effects on readthrough) b) could be fit in a Twist Biosciences Oligopool at an affordable price. For the NTCs library, we took the stop codon sequence for all human protein coding genes.
Data exclusions	Sequencing reads that did not pass the QC filters using DiMSum v1.2.9 (https://github.com/lehner-lab/DiMSum) were excluded. For model generation, variants with very low read coverage (<10 reads) were discarded.

Replication	All sort-sequencing experiments were performed in duplicates. All attempts at replication were successful.
Randomization	Randomization strategies are used to randomly allocate patients in two or more groups to control for potentially influencing factors which might affect the study outcome. Since we don't conduct experiments neither with animals nor patients, the randomization strategies do not apply.
Blinding	A blind experiment attempts to withdld information which might influence the participants of the study until the end of the experiment. Our study doesn't comprise patients, so blinding strategies were not applied.

Reporting for specific materials, systems and methods

We require information from authors about some types of materials, experimental systems and methods used in many studies. Here, indicate whether each material, system or method listed is relevant to your study. If you are not sure if a list item applies to your research, read the appropriate section before selecting a response.

Materials & experimental systems

Methods

n/a	Involved in the study	n/a	Involved in the study
\boxtimes	Antibodies	\ge	ChIP-seq
	Eukaryotic cell lines		Flow cytometry

Eukaryotic cell lines

Plants

Policy information about cell lines and Sex and Gender in Research

Cell line source(s)	TetBxB1BFP-iCasp-Blast Clone 12 HEK293T (Matreyek et al., 2020, Nucleic Acid Res; from Douglas M Fowler lab, University of Washington), HeLa (ATCC), MCF7 (ATCC)
Authentication	The cell lines were not authenticated
Mycoplasma contamination	Cell lines were monthly tested for mycoplasma infection. All tests were negative.
Commonly misidentified lines (See <u>ICLAC</u> register)	We didn't use any commonly misidentified cell lines.

Flow Cytometry

Plots

Confirm that:

The axis labels state the marker and fluorochrome used (e.g. CD4-FITC).

The axis scales are clearly visible. Include numbers along axes only for bottom left plot of group (a 'group' is an analysis of identical markers).

All plots are contour plots with outliers or pseudocolor plots.

A numerical value for number of cells or percentage (with statistics) is provided.

Methodology

Sample preparation	TetBxB1BFP-iCasp-Blast Clone 12 HEK293T cells were grown on standard culture plates in DMEM supplemented with 10% FBS tetracycline-free and without antibiotics. They were split before reaching confluency to maintain cell health. Cells were detached with Trypsin, spun down and washed with PBS. For the sort-seq experiments, cells were treated with doxy to induce the expression of the transcript, and after 24hrs the drug was added to the medium for 48h more. We used high volumes of cells to ensure that each variant was represented >100 times in the cell population. Before sorting, the same amount of cells as those sorted in each bin were withdrawn for sequencing as a pre-sorting control.	
Instrument	BD Influx (TM) Cell Sorter	
Software	BD FACS (TM) Software (1.0.0.650).	
Cell population abundance	The percentage of EGFP+/mCherry+ population was very variable across drugs, ranging from 9% (in untreated conditions) up to 80% (in SRI treatment). Also, the percentage of cells in each of the EGFP+/mCherry+ subpopulations (gates) was very	

variable across drugs. Purities were determined by sorting the cells and then resorting each of the gates separately. Purity was quantified as the number of cells that, when resorted, fell within their gate of origin. Purities were very high across treatments (~85-90%), and more specifically were higher in the upper gates than in the lower gates, because the width of the gates is higher for the upper than for the lower gates.

Gating strategy

Cells were gated by forward scattering area and by side scattering area to retain whole cells, forward scattering width and height to separate discard aggregates, and by DAPI-staining to retain only recombined and alive cells. EGFP and mCherry fluorescence were excited with a 488nm and 561nm lasers and recorded with a 530/40 BP and 593/40 BP channels, respectively. EGFP+ cells were sorted based on mCherry expression into four populations. For most of the populations, 400K cells were sorted. However, for some minor populations representing <2% of the total population, we sorted less cells (100-200K)

X Tick this box to confirm that a figure exemplifying the gating strategy is provided in the Supplementary Information.
