Keywords: Molybdenum carbide MXenes Stacking Surface termination Reverse water gas shift Kinetics Density functional theory Microkinetic modeling

ABSTRACT

Pristine Mo₂C MXene has been recently highlighted as a highly active and robust catalyst for the reverse water gas shift (RWGS) reaction. Here, first-principles calculations based on density functional theory (DFT) coupled with mean-field microkinetic (MKM) simulations are performed to investigate the effects of the atomic layer stacking and the surface functionalization with oxo groups on the catalyst performance. The calculated data show that ABA stacked MXene has a reactivity higher than the corresponding ABC counterpart. Moreover, a $^{2}/_{3}$ surface monolayer oxygen coverage on both stackings (*i.e.*, Mo₂CO_{4/3} MXene) enhances the overall reactivity compared with their pristine Mo₂C counterparts. The reactivity enhancement is small for the more stable ABAstacked model, with a CO gas production aligned with experimental reports. However, the partial O-surface termination in the MXene with ABC stacking offers a more enhanced reactivity, supported by the higher CO gas production for the Mo₂C MXene models here considered. Thus, the MXene stacking and its functionalization are key aspects affecting the performance of the Mo₂C MXene for the RGWS reaction, which must be considered for realistic catalytic applications of MXenes.

1. Introduction

Anthropogenic carbon dioxide (CO₂) emissions are the main contributor to the greenhouse effect, given the ever-growing CO₂ concentration rise in the atmosphere during the last decades [1]. This causes severe environmental problems that threaten mankind, such as ocean acidification, global warming, and glaciers melting, to name a few [2,3]. Therefore, the reduction of CO₂ concentration is among the core action lines in any climate remediation agenda and has become one of the biggest challenges for the scientific community, with many research endeavors placed on carbon capture and storage (CCS) and utilization (CCU) technologies [4]. In principle, CCU-based technologies are more appealing than CCS since the former aim is to convert CO₂ into other valuable and ideally environmentally friendly chemicals [5].

Heterogeneous catalysts suited for CCU platforms are in high demand to achieve the planned targets of green and sustainable chemistry [6]. Among the different CO₂ upgrading processes [7], the reverse water gas shift (RWGS) reaction $-CO_2^{(g)} + H_2^{(g)} \rightarrow CO^{(g)} + H_2O^{(g)}$; $\Delta G^{\circ} = 0.3 \text{ eV}$ at temperature T = 298.15 K— is an appealing and viable route to obtain carbon monoxide (CO) from CO₂ using as reactant hydrogen (H₂), ideally employing H₂ gained using renewable energy sources, such as through the electrochemical water splitting using excess wind or sunlight power. Notably, the overall RWGS has water (H₂O) as the only by-product. The obtained CO can be subsequently used in the downstream Fischer-Tropsch (FT) reaction or methanol synthesis processes [8–11], again especially attractive when using *green* H₂. The endergonic nature of the RWGS requires high temperatures to achieve CO₂ conversion, and that is why it is peremptory to use highly active and selective catalysts to imbalance the C–O dissociation and hydrogenation steps as well as to operate under working conditions as mild as possible.

Usual RWGS catalysts consist of metal active sites, *i.e.*, Cu, Pt, Pd, or Rh, well dispersed on high-surface metal oxide supports, such as CeO₂,

often used due to its excellent redox properties [12–15], or other oxides such as TiO_2 and ZnO [16,17]. Given the scarcity and high cost of the late transition metals, transition metal carbides (TMCs) have also been explored as efficient and more economic catalysts for the RWGS, in line with the similar activity of noble metals and poisoning resistance [18–20]. Indeed, TMCs have also been regarded as supports of transition metals for the RWGS, adjoining synergistic effects between metal and support [21].

The observed outstanding catalytic performance demonstrated by TMCs on the RWGS opened the way for exploring the performance of their two-dimensional (2D) counterparts, the so-called MXenes [22]. First isolated in 2011, these materials have significantly impacted many scientific fields due to their unique properties and composition tunability through surface functionalization and elemental composition [22,23]. MXenes have a general $M_{n+1}X_nT_x$ chemical formula and are generally derived from MAX phases by selective etching of the A element, although layer growth paths have been proposed [24,25]. The M, X, and T_x labels represent an early transition metal, carbon and/or nitrogen, and the surface functionalization (-O, -OH, -H, or -F), respectively, while n = 1-4 represents the thickness of the material measured in number of atomic layers of the X element [26,27]. Regarding surface termination, novel synthetic routes or treatment protocols have shown how to gain unfunctionalized (or bare) MXenes [28-30].

Pristine MXenes have shown excellent CCS capabilities, as confirmed by both molecular simulations and experiments [29,31]. Furthermore, MXenes also feature a high affinity towards H₂, catalyzing its dissociation, often spontaneously, and posing themselves as suitable catalytic materials for hydrogenation reactions [32]. Moreover, CO₂ dissociation into CO + O —usually the reaction limiting step— is feasible on MXenes, requiring overcoming low kinetic energy barriers of up to 0.6 eV [33]. The above outlined possible uses of MXenes as heterogeneous catalysts for CCU technologies are not limited to the RWGS reaction [33]. For instance, partially O-covered Mo₂C MXene has been pointed out as an effective heterogeneous catalyst for the methane dry reforming [34] or for the Fischer–Tropsch Synthesis [9], and even as a support for Cu single atoms in the CO₂ reduction to methanol [35].

Recently, Jurado *et al.* [36] investigated the RWGS as heterogeneously catalyzed by pristine Mo₂C MXene, combining first-principles calculations and microkinetic simulations. While the redox and formate routes were the most plausible pathways for the reaction mechanism, H₂O formation was found to be the rate-limiting step [37], even though optimal CO formation was achieved at ~600 K and low total pressure of 1 bar, in line with subsequent experimental observations on a cleaned Mo₂C MXene, with a peak RWGS performance at *ca.* 700 K and 1 bar [38], hence with capabilities to outperform the industrial benchmark Cu-ZnO-Al₂O₃ catalyst in terms of activity, selectivity, and/or stability.

Although these are promising results, there are aspects of the mechanism of the RWGS reaction catalyzed by Mo₂C that are missing, yet necessary to reach a rational-driven significant advance in conversion optimization. In particular, two main questions remain hitherto unsolved. On the one hand, it has been observed that the CO production during the RWGS is minimal for as-prepared Mo₂CT_x samples; this is, with no treatment of surface functional groups, e.g., -O, whereas the sample treatment at 500 °C with H2 ----to remove surface --- O groups and leave the surface clean- significantly impacts the catalytic performance, raising the CO production by two orders of magnitude, and reaching the performance levels of reference Cu-ZnO-Al₂O₃ catalyst. Thus, the presence/absence of surface -O groups biases the catalytic reaction, but the underlying chemistry is unknown. On the other hand, it is now well known that MXenes, when extracted from a MAX matrix, do not necessarily follow the same ABC layer stacking of the parent MAX phase. There is computational and experimental evidence that, for some MXene compositions, a phase transition towards ABA can be energetically and kinetically prompted [39], also influenced by the termination.

Clearly, this may have an impact on the overall surface chemical and catalytic activity [40]. Here, we address these two aspects by performing theoretical calculations based on density functional theory (DFT), combined with microkinetic simulations. These allows us to univocally assess the effect of the O surface termination and of the atomic layer stacking on the RWGS mechanism and catalytic performance on Mo₂C MXene-based catalysts.

2. Computational strategy and models

The RWGS reaction mechanism was investigated over the Mo₂C (0001) MXene pristine and partially O-functionalized surfaces. The basal (0001) plane of the Mo₂C MXene is represented by a $p(3\times3)$ supercell (Fig. 1), large enough to host the reactants, intermediates, and products involved in the RWGS reaction [33,36]. Diverse high-symmetry sites —top, bridge, or hollow sites— were tested for the adsorption of reactants, intermediates, and products regarding different connectivity, orientations, and conformation. Due to the periodic boundary conditions, a vacuum of at least 10 Å along the [0001] direction was included to avoid the interaction between the periodic MXene replicas in this direction.

For the pristine case we focus on the ABA atomic layer stacking (Mo₂C-ABA model) thus complementing a previous study which considered the ABC stacking (Mo₂C-ABC model) [36]. The stability of the ABA-stacked material when compared to the ABC-stacked one is a well-established result from previous studies [39,41,42]. For the partially O-functionalized Mo₂C (*i.e.* Mo₂CO_{4/3} as the two surfaces have a $^2/_3$ O coverage), both ABA (Mo₂CO_{4/3}-ABA model) and ABC (Mo₂CO_{4/3}-ABC model) atomic layer stackings are considered, see Fig. 1. In the case of –O termination, the –O atoms are located at the three-fold hollow sites, following the same stacking definition as the inner C layer, as this is found to be their optimal position [43]. The O coverage considered involves occupancy of $^2/_3$ of the surface hollows sites as in previous studies [34,35] (*cf.* Fig. 1c). The clustering of pristine sites on the model catalyst surfaces is also justified in terms of stability;

Fig. 1. Top (top) and side (bottom) views of the a) pristine (0001) Mo₂C MXene surface with ABC stacking, b) pristine (0001) Mo₂C MXene surface with ABA stacking, c) partially O-terminated Mo₂C MXene (0001) surface with $^{2}/_{3}$ of a monolayer (ML) of –O coverage per surface, with BABAB stacking, and d) partially O-terminated Mo₂C MXene surface model with BABCB stacking. The solid yellow line defines the employed $p(3 \times 3)$ supercell. C, Mo, and O atoms are depicted by gray, green, and red spheres, respectively.

see discussion in Section S1 and Fig. S1 of the Supporting Information (SI). The presence of oxygen on the surface of the MXene is stable and derived from its synthesis procedure. A cleaning-up procedure requires the H₂ exposure at 700 °C (*ca.* 1000 K) to remove oxygen as water. This experimental evidence, together with computational studies, reveals that O-free situations are attainable only at very high temperatures and supports the notion that the present $^2/_3$ monolayer (ML) coverage model is reasonable at the evaluated reaction conditions.

The adsorption energy of the *i* species, E_{ads}^{i} , is defined as;

$$E_{\rm ads}^i = E_{i/\rm MXene} - (E_i + E_{\rm MXene}) + \Delta ZPE, \tag{1}$$

where $E_{i/MXene}$ represents the total energy of species *i* adsorbed on the *p* (3×3) MXene supercell; E_{MXene} is the total energy of the $p(3\times3)$ MXene supercell depicted in Fig. 1 --either the unfunctionalized Mo₂C-ABA stacking model, or the partially O-functionalized Mo₂CO_{4/3}-ABA or $Mo_2CO_{4/3}$ -ABC stacked models—, and, finally, E_i stands for the total energy of the isolated *i* species optimized in an asymmetric box of $10 \times 11 \times 12$ Å dimensions, carried out at Γ -point only. Δ ZPE corresponds to the zero-point energy (ZPE) change between the adsorbed and gas phase species. For this term, vibrational frequencies are needed, either for the gas phase molecule or for the adsorbed species, in the latter case disregarding coupling with Mo₂C or Mo₂CO_{4/3} phonons. For the adsorbed species, vibrational modes from frustrated translational and rotational degrees of freedom are accounted for. The diagonalization of the Hessian matrix with elements computed as finite differences of analytical gradients with displacements of 0.015 Å was carried out to obtain such frequencies.

To facilitate a consistent comparison of the present results with those in previous work [36], we followed the very same computational strategy carrying out periodic DFT calculations as implemented in the Vienna ab initio simulation package (VASP) [44] and using the same computational setup. Thus, the Perdew-Burke-Ernzerhof (PBE) density functional [45], belonging to the generalized gradient approximation (GGA) family, has been used to account for the exchange and correlation effects. Note that this density functional has shown an excellent performance in describing bulk three-dimensional molybdenum carbide systems [46]. The broadly employed and suited Grimme's D3 approach [47] was used to account for the dispersion interactions [48]. The effect of the core electrons on the valence density was described using the projector augmented wave (PAW) method [49], while a plane-wave basis set with a 415 eV cutoff energy was selected to expand the valence electron density. The numerical integration in the reciprocal space was carried out using a Γ -centered 5×5×1 k-point grid in the Brillouin zone. Forces below 0.01 $eV \cdot A^{-1}$ on all atoms and relaxation of the electronic degrees of freedom with a 10^{-6} eV threshold ensure numerical accuracy below 0.04 eV in the geometry optimization calculations, thus close to the chemical accuracy limit [31–33].

Once the minimum energy structures were obtained and characterized, a transition state (TS) search was carried out employing the Dimer method, and minimizing forces acting on atoms below 0.01 eV·Å⁻¹ [50]. The frequency analyses were also employed here to confirm the saddle point character of TSs, with only a single imaginary frequency along the reaction path. The activation energy barriers, $E_{\rm b}$, of the different reaction steps were obtained as the difference between the ZPE-corrected energies of the TS and of the initial state (IS) configurations. The rate parameters —*i.e.* the equivalent of rate constants in formal kinetics were obtained from transition state theory as

$$r = \frac{k_{\rm B}T}{h} \cdot \frac{Q_{\rm TS}}{Q_{\rm IS}} \cdot e^{\left(-\frac{E_{\rm b}}{k_{\rm B}T}\right)},\tag{2}$$

where $k_{\rm B}$ and h are the Boltzmann's and Planck's constants, respectively, while $Q_{\rm TS}$ and $Q_{\rm IS}$ are the partition functions of the TS and IS, respectively. Further details on their expression for the ZPE-corrected $E_{\rm b}$ can be found in the literature [51]. The desorption rates were estimated assuming late TSs, *i.e.*, $E_{\rm b} = -E_{\rm ads}$, and a two-dimensional translational and a rotational partition function applied on Q_{TS} [51]. The adsorption rate, r_{ads} , though, was derived from collision theory employing the Hertz-Knudsen equation [52] as;

$$r_{\rm ads} = \frac{A_{\rm site} \cdot p_{\rm i} \cdot S_{\rm i}}{\sqrt{2 \cdot \pi \cdot m_{\rm i} \cdot k_{\rm b} \cdot T}},\tag{3}$$

where A_{site} is the area of the adsorption site calculated dividing the supercell area of the MXene surface by the total number of sites in it [53]; p_i corresponds to the partial pressure of the *i* component; S_i corresponds to the sticking coefficient of the *i* component; and m_i is the molecular mass. Here, the sticking coefficient of reactants and products was fixed to unity based on previous estimations of this parameter for these molecules on Pt surfaces ($S_i \sim 0.7$), on which the adsorbate-adsorbent interactions were of the same order of magnitude [54–56].

The rate parameters described above were used to carry out meanfield microkinetic (MKM) simulations, allowing one to identify the rate-limiting steps of the RWGS reaction for each studied case. All MKM simulations were carried out using the MKMCXX code [57,58], and assuming the quasi-equilibrium approximation. Under these circumstances, one can obtain the surface coverage, θ , for each *i* species and the overall reaction rate. During the catalytic reaction, the adsorption, desorption, and reaction steps are the main occurring processes. Finally, the present MKM simulations neglected the interaction between non-reacting adsorbed species, and they are assumed to be randomly distributed over the derived Mo₂C MXene surface and always available. Such MKM limitations can be overcome with further analysis using kinetic Monte Carlo simulations, including the spatial display of surface chemical moieties and their lateral interactions.

3. Results and discussion

Let us start tackling the stacking —ABA or ABC— effect on relevant properties by comparing adsorption energy differences for reactant —CO₂ and H₂— or product —CO and H₂O— molecules. The results for the bare Mo₂C (0001) surfaces are compiled in Table 1, and show that

Table 1

Relevant energy quantities for the elementary reaction steps of the RWGS reaction on the Mo₂C (0001) surface models with ABA or ABC stacking. The ABC stacking values are taken from Ref. [36]. Activation energy barriers, E_b (in eV) for forward (*fwd*) and backward (*bwd*) reactions, are included together with the reaction energies or energy changes, ΔE (in eV). Note that $\Delta E_{fwd} = -\Delta E_{bwd}$. For completeness, adsorption/desorption steps for CO₂, H₂, CO, and H₂O are included. All provided values provided include the ZPE term.

 CO_2 molecule adsorption is exothermic by -1.80 or -0.94 eV for ABC or ABA stacking, respectively, displaying a geometry consistent with the so-called activated CO₂. For the ABA stacking, the calculated C-O bond lengths of adsorbed CO₂ are 1.34 and 1.25 Å, elongated as previously reported for the ABC stacking with values of 1.51 and 1.26 Å [31]. On the ABC (ABA) surface, H2 adsorbs molecularly with an adsorption energy of -0.92 (-0.62 eV) and an elongated molecular bond of 0.89 Å (0.85 Å), compared to the value of 0.75 Å in the gas phase, and thus in line with a Kubas adsorption mode [59,60]. Concerning the products, CO features the largest E_{ads} with values of -2.39 and -1.83 eV for Mo₂C with ABC and ABA stacking, respectively. Finally, the H₂O molecule interacts weakly, with E_{ads} values of -0.95 and -0.63 eV. All in all, the results clearly show that the Mo₂C (0001)-ABC surface model has a higher chemical activity compared to Mo₂C-ABA, with enhanced adsorption energies by 0.30-0.86 eV, in concordance with Mo₂C-ABC being less stable than Mo₂C-ABA [39], and therefore, more prone to adsorb species upon to compensate its inherent instability, as observed previously on TMC surfaces [61]. From Le Sabatier principle, the ABA stacking would be a better catalyst for the RWGS, adsorbing species in a more moderate fashion.

Regarding partially O-covered models ($Mo_2CO_4/3$), the reactants adsorb much more weakly than on the bare Mo₂C models, as shown in Table 2. In particular, when going from the bare Mo₂C to the partially Ocovered Mo₂CO_{4/3} surface, the CO₂ adsorption energies for Mo₂CO_{4/3}-ABC (Mo₂CO_{4/3}-ABA) change from -1.80 (-0.94) to -0.18 (-0.31) eV. This implies that, in the presence of the O surface termination, the ABAstacked MXene becomes the most active towards CO2 adsorption, although by a small margin. In turn, H₂ adsorption energies on partially O-covered Mo₂C, -0.07 (-0.06) eV, are around a tenth of the ones calculated for the bare ABC (ABA) surface and do not change with the atomic layer stacking of the material. Concerning the reaction products, H₂O adsorption strength does not change much with either the O coverage or the stacking, as its adsorption energy on ABC (ABA) partially O-covered surface are -0.75 (-0.73) eV, which are similar to the ones found for bare Mo₂C. In these three cases —CO₂, H₂, and H₂O stacking has nearly no effect, given they are essentially physisorbed, which are known to be surface-insensitive. The exception is CO, which remains quite strongly adsorbed in the vicinity of the O surface groups, changing from -2.11 eV on Mo₂C on average to -1.80 (-1.23) eV on the Mo₂CO_{4/3}-ABC (Mo₂CO_{4/3}-ABA). This again poses the more stable ABA stacking as the less active surface, as for pristine Mo₂C models. Overall, the activation of CO and CO₂ molecules is significantly more exothermic on bare Mo₂C supports, while the activation of H₂O and CO is more exothermic on Mo₂CO_{4/3}, regardless of the stacking. These differences in the adsorption of reactants and products have an impact on the catalyst

Table 2

Relevant energy quantities for the elementary reaction steps of the RWGS reaction on the Mo₂CO_{4/3}(0001) surface models with ABC or ABA stacking. Activation energy barriers, $E_{\rm b}$ (in eV) for forward (*fwd*) and backward (*bwd*) reactions, are included together with the reaction energies or energy changes, ΔE (in eV). Note that $\Delta E_{\rm fwd} = -\Delta E_{\rm bwd}$. For completeness, adsorption/desorption steps for CO₂, H₂, CO, and H₂O are included. All provided values provided include the ZPE term.

production, as will be discussed below with reference to the results of the microkinetic modelling.

These activity trends are generally kept when drawing the reaction energy profiles. Here, the existence of two well-defined reaction routes [36] is worth highlighting: The so-called redox mechanism, where CO₂ adsorbs and dissociates into CO⁺ + O⁺ —^{*} denoting a surface site—, and O^{*} gets hydrogenated leading to H₂O, see Fig. 2, and the associative mechanism, where CO₂ gets hydrogenated first. Regarding the associative mechanism, two sub-routes depend on whether the C atom or the O atom of CO₂ gets hydrogenated first, leading to formate (HCOO⁺) or carboxyl (COOH⁺) intermediates, respectively. As shown in Fig. 2, formate can dissociate into HCO^{*} and O^{*}, and the resulting HCO^{*} species subsequently dissociates into H⁺ and CO⁺, thus leading to an alternative formate-mediated CO₂^{*} dissociation. In the case of carboxyl, usually, two isomers may exist on the surface, the *trans*- and *cis*-COOH⁺, which can dissociate into CO^{*} + OH^{*}. This route avoids forming O^{*} at any stage, as the OH^{*} can be hydrogenated towards H₂O^{*}, see Fig. 2.

The three RWGS reaction routes were thus investigated on the bare Mo_2C-ABC and Mo_2C-ABA models, while on partially O-covered $Mo_2CO_{4/3}$ -ABA and $Mo_2CO_{4/3}$ -ABC, only the redox mechanism was considered; explained in detail below. Previous works [33,34,38] have shown that bare MXenes excel at dissociating chemical species into individual atoms, whereas, concomitantly, they have a hard time carrying out the reverse process. The RWGS involves bond-breaking in the early stages and bond-formation in the later ones. Therefore, one should expect the adsorption and dissociation steps to be thermodynamically and kinetically driven and the desorption and associative steps less keen to occur. As the calculations show, CO_2 dissociation will likely proceed without prior hydrogenation. In contrast, the hydrogenation of the resulting O* is likely energy-demanding, hinting that the RWGS redox route is most favorable.

The reaction energy profiles of RWGS via the redox mechanism on the four Mo_2C MXene surfaces considered here are shown in Fig. 3 and confirm the above predictions. As can be seen, the calculated CO_2

Fig. 2. Schematic view of the RWGS mechanism, including redox, formate, and carboxyl routes depicted by black, red, and green lines, respectively. The rectangles represent the surface, and the circles represent atoms of hydrogen (white), carbon (grey), or oxygen (red). Adsorbed situations are marked with a surface-active site, *.

Fig. 3. RWGS reaction energy profile —including ZPE— *via* the redox mechanism, as catalyzed by pristine yet differently stacked Mo₂C-ABA and Mo₂C-ABC (0001), and partially O-terminated Mo₂C (0001) surfaces, Mo₂CO_{4/3}-ABA or Mo₂CO_{4/3}-ABC. TS1, TS2, TS3, and TS4 denote the TSs of steps **5-8** of Tables 1 and 2.

dissociation energy barriers on Mo₂C-ABA and partially O-covered Mo₂CO_{4/3}-ABA and Mo₂CO_{4/3}-ABC, with transition state denoted TS2 in Fig. 3, are indeed negligible, of at most 0.03 eV as gathered in Tables 1 and 2. This contrasts with the same barrier on Mo₂C-ABC (0.47 eV). Reaction energy plots in Fig. 3 hint that, from the four surfaces shown, the partially O-covered Mo₂CO_{4/3}-ABA would be the most suited for catalyzing the RWGS through the redox path, with very low H₂ and CO₂ dissociation barriers while featuring the most moderate reaction exothermicity and adsorption energies. In contrast, the other RWGS routes on Mo₂C-ABC and Mo₂C-ABA involve energy barriers around 0.7 eV or more (cf. Table 1) to form the intermediate species between the CO_2^* and CO^*+O^* stages. Energy barriers around 0.7 eV are not prohibitive, but the nearly spontaneous CO₂ dissociation on all surfaces except Mo₂C-ABC is more favored. The reaction energy profiles for the formate and carboxyl routes are given in Figs. S2 and S3 of the SI. In turn, H₂ dissociates practically spontaneously upon adsorption on all four surfaces studied (cf. Tables 1 and 2), showing that H₂ will be prone to better interact and dissociate on pristine MXene sites rather than on Mo-O sites on the O-covered models.

Still, the above reaction energy profiles and discussion only hint at the reaction kinetics. To better assess the reaction kinetics, a series of MKM simulations have been carried out. MKM aims to analyze the influence of working conditions -temperature, T, and gases partial pressures, p_i — on the catalyst production, here seized by the turnover frequency, TOF. The numerical integration is carried out subject to initial conditions from time t = 0 s until steady state, *i.e.*, the surface coverages no longer changing with time. To facilitate the comparison with previous studies [36], a H₂:CO₂ ratio of 2:1 is selected, also supported by available experimental data [62,63]. In the MKM simulations, all available elementary reaction steps --from redox, carboxyl, and formate routes- are considered, as compiled in Table 1, including forward (fwd) and backward (bwd) activation energy barriers, E_{b} , and the reaction energy changes, ΔE , for pristine Mo₂C MXenes with ABA and ABC stackings, while equivalent partially O-covered values are shown and discussed below.

Attention is driven first to the coverage evolution of the different reaction species as a function of *T*, see Fig. 4. At first sight, the RGWS reaction on Mo₂C-ABC involves more intermediates in the temperature range of 300–650 K when compared to Mo₂C-ABA which is relatively less complex. At a very low temperature of 300 K, the Mo₂C-ABC model is mainly covered by H adatoms resulting from H₂* dissociation. Any adsorbed CO₂ becomes hydrogenated to form HCOO*, which is, in principle, prompted by the high H* coverage. On Mo₂C-ABA, though, despite the high H* coverage, one would expect less HCOO*; since E_b for Mo₂C-ABC is 0.56 eV, whereas it is 0.73 eV for Mo₂C-ABA. However,

Fig. 4. Surface coverage evolution with *T* for the RGWS reaction on the Mo₂C (0001) surface with ABC (top) and ABA (bottom) stacking. Coverages were taken with input H_2 :CO₂ 2:1 ratio and a total pressure of 1 bar. The results concerning the ABC-stacked surface were taken from Ref. [36].

equal parts of HCO^{*} and O^{*} are found, in line with the very easy HCOO^{*} decomposition on the Mo₂C-ABA model, with an E_b below 0.01 eV, compared to the 0.29 eV barrier on Mo₂C-ABC.

On both models, above T = 350 K, H* vanishes, either consumed in any reaction mechanism or backreacted towards H₂* and desorbed. Also, the CO₂* + H* \rightarrow HCOO* \rightarrow HCO* + O* sequence of elementary steps seems to be followed, with a certain existence of HCOO* on Mo₂C-ABC, in principle due to an easier formation of this species, either from the forward ($CO_2^* + H^*$) or backward ($HCO^* + O^*$) reactions when compared to Mo₂C-ABA. At T > 400 K, the redox route opens, as observed by an excess of O* with respect to HCO* and the appearance of CO* by essentially equal amounts. By raising the temperature, the redox route gains relevance on both Mo₂C-ABC and Mo₂C-ABA models, while formate loses the leadership, even if HCOO* presence is kept on the Mo₂C-ABC model. The main difference is the peak of CO* presence, achieved at 450 K for Mo₂C-ABA and 550 K for Mo₂C-ABC. From such temperatures, a saturation of O* is achieved on both models, at 500 K for Mo₂C-ABA and 650 K for Mo₂C-ABC. Altogether, there is a parallelism of ABA and ABC kinetics in *i*) the low-temperature preference for formate associative mechanism, ii) the opening of redox mechanism at 400 K, and iii) the main relevance at temperatures above 400 K, until iv) a critical temperature at which the Mo₂C surface becomes fully occupied by O atoms. However, it is worth noting that the reactive stages on Mo_2C -ABA are found at temperatures ~100 K lower than on Mo_2C -ABC.

The above discussion relates only to surface species, and the formation of $CO^{(g)}$ and $H_2O^{(g)}$ products needs also to be assessed. This is tackled in Fig. 5 reporting turnover frequencies (TOFs) heating contour maps of CO^(g) production using H₂:CO₂ ratio of 2:1 on Mo₂C-ABC and Mo₂C-ABA models. For completeness H₂O^(g) production is depicted in Figs. S4 and S5 of the SI. The ABC stacking features the largest CO production in the 550–620 K temperature range, highlighted in Fig. 5 by yellow stripe, with a peak of $3.37 \cdot 10^{-3}$ molecules site⁻¹ · s⁻¹ at 1 bar of total pressure [36]. At this temperature and pressure, the ABA stacking performance is seven orders of magnitude lower, 2.53.10⁻¹⁰ molecules-site⁻¹·s⁻¹, and higher temperatures of ~800 K are required to achieve a comparable (or even greater) CO^(g) production. In fact, a much higher TOF, of about 0.41 molecules site⁻¹·s⁻¹, is achieved on Mo₂C-ABA at 1 bar and 850 K, while at the same conditions, Mo₂C-ABC performs worse with a TOF of $3.26 \cdot 10^{-6}$ molecules site⁻¹ · s⁻¹. On the Mo₂C-ABA model, the performance slightly increases with total pressure, to 3.47 molecules site⁻¹·s⁻¹ at 850 K and 10 bar (further details in Tables S1 and S2). Note that the TOF achieved at 500 K and 7 bar is found to be a numerical artefact derived from the microkinetic analysis. The highest performances of either Mo₂C-ABC or Mo₂C-ABA at temperatures around 600 or 800 K, respectively, are in line with the experimental highest peak at ca. 700 K [38], knowing that mean-field MKM simulations can deviate peak performances by \pm 100 K [64].

We now drive the discussion to the impact of having a partial Otermination on the examined MXene models. This is spurred by the experimental key performance also previously suggested using theory [34] for $^{2}/_{3}$ ML of surface –O groups [34,38] at each surface, by the O-affinity of both Mo₂C-ABA and Mo₂C-ABC surface models at high temperatures, and by the present observation of the peak performance when having a partial O* coverage as observed on pristine ABC, see Figs. 4 and 5. Note here in passing that the stacking notation for Mo₂CO_{4/3}-ABA and Mo₂CO_{4/3}-ABC models is BABAB and BABCB, respectively, see Fig. 1. As observed in Fig. 6 for CO^(g) production, and on Figs. S6 and S7 of the SI for H₂O(g) production, in general terms, the activity of the Mo₂CO_{4/3} (0001) surface models get reduced when having such an O* coverage, as above commented, also reducing the difference between stackings, with only CO featuring a markedly stronger bonding on Mo₂CO_{4/3}-ABC.

As commented above, the essentially barrierless CO_2^* dissociation step, either for $Mo_2CO_{4/3}$ -ABC or $Mo_2CO_{4/3}$ -ABA, prompts the reaction to follow the redox path, with kinetic and thermodynamic values are compiled in Table 2. In addition to CO_2^* dissociation, H_2^* dissociation is also favored with a $^2/_3$ of a ML of -O groups, with E_b values being also essentially barrierless. Thus, again, OH* and H_2O^* formations could be rate-determining steps (RDS) for $Mo_2CO_{4/3}$ -ABC and $Mo_2CO_{4/3}$ -ABA, respectively, with E_b values of 1.41 and 2.16 eV. Actually, as seen in Table 1, H_2O^* formation was already the RDS on pristine Mo_2C -ABC and Mo_2C -ABA models, with E_b values of 1.68 and 1.84 eV, respectively.

Thus, based on the TOF color maps in Figs. 5 and 6, one would expect the RWGS to be slightly favored on Mo₂CO_{4/3}-ABC compared to the pristine case while disfavored on Mo₂CO_{4/3}-ABA. As observed, the better assessment of kinetics by MKM simulations, in Fig. 6 —equivalent Figs. S7 and S8 of the SI for H₂O^(g) production— reveal that the performance is similar for low temperatures, up to *ca*. 650 K on Mo₂CO_{4/3}-ABC and Mo₂CO_{4/3}-ABA models. From this temperature on, the RWGS performance increases for both models, but especially for the ABC one, reaching TOFs three orders of magnitude higher than on Mo₂CO_{4/3}-ABA at a temperature of *ca*. 800 K. Curiously, on Mo₂CO_{4/3}, the hightemperature performance is better achieved on ABC (*cf.* Fig. 6), while the opposite is found on the pristine Mo₂C models (*cf.* Fig. 5).

Additional sensitive analysis of the microkinetic simulations is performed to quantify the uncertainties of the DFT calculations and quantify the effect on the catalytic production. Thus, we focus on the $Mo_2CO_{4/3}$ MXene with ABC stacking at 850 K and 1 bar. At these conditions, the partially O-covered MXene shows the largest TOF values (*ca.* 112 molecules·site⁻¹·s⁻¹, see Table S2 of the SI). To further validate this conclusion, we varied different kinetic and thermodynamic parameters one by one taking as reference our initial microkinetic simulations: First, the TOF was found to sensibly decrease to 17.7 molecules·site⁻¹·s⁻¹ when increasing only the CO₂ dissociation energy barrier by 0.2 eV, in line with typical DFT accuracy. Note, however, that this elementary reaction is here predicted to be barrierless, see Table 2). On the other

Fig. 5. Color map of TOF under different *p* and *T* conditions for the RGWS reaction on the Mo_2C (0001) surface with ABC (left) and ABA (right) stacking for the CO^(g) production. The TOF scale corresponds to the logarithm with base 10. The results concerning the ABC-stacked surface were taken from Ref. [36].

Fig. 6. Color map of TOF under different p and T conditions for the RGWS reaction on the (0001) Mo₂CO_{4/3} MXene surface models with ABC (left) and ABA (right) stacking for the CO production. The TOF scale corresponds to the common logarithm with base 10.

hand, the TOF production significantly increases up to *ca.* 542 molecules-site⁻¹·s⁻¹ when increasing the CO₂ adsorption energy also by just 0.2 eV. Furthermore, a CO desorption energy drop of 0.2 eV (*ca.* 1.60 eV) just slightly increases the TOF up to nearly 210 molecules·site⁻¹·s⁻¹. Finally, artificially decreasing the energy barriers of limiting steps of OH and H₂O formation by 0.2 eV results into negligible variations in the TOF. Such effects are likely translated to the other MXene models, given the similarities in the elementary steps and mechanisms. Thus, from this analysis, it arises the combination of low dissociative energy for the CO₂ molecule and a high exothermic CO₂ interaction, plus an easy CO desorption, are key steps in optimizing the RWGS process.

At this stage, it is worth correlating the obtained TOFs with those from the experiments [38]. There, it was found that a $CO_{(g)}$ production of about 1500 mg CO h^{-1} g_{cat}^{-1} when departing from H₂-treated, pristine 2D-Mo₂C and performing the RWGS at 430 °C (703.15 K). Even if the H₂: CO mixture employed was 3:1 and here 2:1, one can estimate the log TOF of CO, assuming that all the Mo₂C is exposed (even if in the experiments only a part is expose), and that there are two surface active sites per Mo₂C sheet, and that an active site is comprised within the employed $p(3\times3)$ cell. Considering this, a rough estimate for the experimental log TOF is -1.86, while the present MKM simulations for pristine Mo₂C-ABC and Mo₂C-ABA at these conditions are -8.46 and -12.76, respectively. This indicates that the pristine surfaces are far from being adequate catalysts and also that the corresponding theoretical models do not perform well. However, the results for the models with $^{2}/_{3}$ ML –O coverage are much closer to the experiment. In particular, the log TOF of $Mo_2CO_{4/3}$ -ABA of -1.56 is the closest to the experimental value, especially when compared to the Mo₂CO_{4/3}-ABC estimate of -0.12 or the pristine values above, with differences between theory and experiment raising from e.g. the mean-field microkinetic modeling approach, of mass-transport limitations in experiments, here not accounted for. Still, this better agreement of Mo₂CO_{4/3} (0001)-ABA model reconciles theory forecasts with experiments, in that i) ABA is known to be energetically preferred over ABC for the Mo₂C MXene, especially when O-covered [39], ii) the observed better catalytic performance of partially O-covered Mo₂C [35,38], and iii) the need of H₂-pretreatment of Mo₂C to remove surface terminations, even if under operando conditions the catalyst gets partially O-covered [38,64]. Further, the MKM simulations show that the catalyst could benefit from an increased performance by a few orders of magnitude when the Mo₂C MXene could be kept in its ABC stacking, leaving this door open for future catalyst engineering.

4. Conclusions

The present first-principles DFT calculations combined with microkinetic MKM simulations on the RWGS reaction over the (0001) molybdenum carbide MXene surface unfolded the influence of the MXene stacking and the partial –O termination over the resulting CO gas production. The results show that CO gas production can occur at mild reaction conditions of pressure, gas mixture, and temperature, where the formation and release of water is the limiting step. The pristine Mo₂C MXene models feature higher chemical activity than the partially Oterminated counterparts, especially when the reaction occurs on the less stable ABC stacking, prompting the rapid dissociation of reactants but also the more costly product formation.

Based on MKM simulations, pristine Mo₂C-ABA MXene leads to higher TOF values than its ABC counterpart at a temperature above 800 K, while ABC stacking promotes higher production than the ABA one at 600 K. Even if the associative mechanism is followed at low temperatures, the redox path is the main reaction route at higher temperatures on any Mo₂C stacking. This leads to the catalyst being covered by O adatoms.

The partial –O coverage significantly increases the CO gas production following the redox mechanism on the $Mo_2CO_{4/3}$ -ABC model, surpassing the performance of the $Mo_2CO_{4/3}$ -ABA one, however, the latest is a priori more stable and closer to the reported experimental TOF. Therefore, this study suggests that the catalytic performance of the molybdenum carbide MXene for the reverse water gas shift reaction can be increased by guiding its synthesis to favor the ABC stacking and a partial termination of its surface with oxygen atoms. Possibly most importantly, a key message of this work is that the atomic layer stacking and surface termination of a MXene must not be ignored when computationally studying catalysis on MXenes to realistically tackle experimental reactions.
