Title: Vegetation dynamics at Raraku Lake catchment (Easter Island) during the past 34,000 years

Article Type: Research Paper

Keywords: Easter Island; Rapa Nui; vegetation responses; climate changes; late Quaternary

Abstract: Easter Island is a paradigmatic example of human impact on ecosystems. The role of climate changes in recent vegetation shifts has commonly been rejected without proper assessment. A palynological study in a long record from Raraku Lake documents the vegetation dynamics for the last 34 ka and investigates their driving forces, particularly the effects of climate variability on vegetation cover. Significant relationships with sedimentary and geochemical proxies demonstrate the rapid response of vegetation to lake crater basin hydrology and climatic changes. The lake surroundings were occupied by an open mixed palm grove during the last glacial period. Poaceae and *Sophora* increased at the expense of palms and *Triumfetta*, and *Coprosma* practically disappeared, in response to slightly wetter and/or colder climate during the Last Glacial Maximum. Palms and *Triumfetta* thrived in a warmer and/or drier climate during the deglaciation. Small vegetation changes (a slight increase in *Sophora* and a drop in Asteraceae and Poaceae) occurred between 13.2 and 11.8 cal ka BP and can be related to rapid changes in the Younger Dryas chronozone. The increase in herbaceous taxa indicates a terrestrialization of the mire during the Holocene, caused both by warmer and drier climate and by a shallowing trend due to sediment infilling. Relatively rapid vegetation changes in the Holocene were caused by climate and by plant succession in the shallowing mire. The rates of vegetation change observed in the mire were similar to those at the initial stages of human impact identified in a previous study. These results reveal significant vegetation changes prior to human presence, due to the interplay of climate variations (temperature and moisture), changes in lake basin form by infilling and intrinsic dynamics in plant succession. Hence, the potential contribution of these factors in vegetation shifts during the period of human presence should not be downplayed.

20 **ABSTRACT**

21 Easter Island is a paradigmatic example of human impact on ecosystems. The role of climate
22 changes in recent vegetation shifts has commonly been rejected without proper assessment. A
23 palynological study ~~in~~ a long ~~record~~ from Raraku Lake documents the vegetation dynamics for
24 the last 34 ka and investigates their driving forces, particularly the effects of climate variability
25 on vegetation ~~cover~~. Significant relationships ~~with~~ sedimentary and geochemical proxies
26 demonstrate the rapid response of vegetation to lake crater basin hydrology and climatic
27 changes. The lake surroundings were occupied by an open mixed palm grove during the last
28 glacial period. Poaceae and *Sophora* increased at the expense of palms and *Triumfetta*, and

29 *Coprosma* practically disappeared, in response to slightly wetter and/or colder climate during
30 the Last Glacial Maximum. Palms and *Triumfetta* thrived in a warmer and/or drier climate
31 during the deglaciation. Small vegetation changes (a slight increase in *Sophora* and a drop in
32 Asteraceae and Poaceae) occurred between 13.2 and 11.8 cal ka BP and can be related to rapid
33 changes in the Younger Dryas chronozone. The increase in herbaceous taxa indicates a
34 ~~terrestrialization of the mire during the Holocene, caused both by warmer and drier climate and~~
35 ~~by a shallowing trend due to sediment infilling.~~ Relatively rapid vegetation changes in the
36 Holocene were caused by climate and by plant succession in the shallowing mire. The rates of
37 vegetation change observed in the mire were similar to those at the initial stages of human
38 impact identified in a previous study. These results reveal significant vegetation changes prior
39 to human presence, due to the interplay of climate variations (temperature and moisture),
40 changes in lake basin form by infilling and intrinsic dynamics in plant succession. Hence, the
41 potential contribution of these factors in vegetation shifts during the period of human presence
42 should not be downplayed.

48 1. INTRODUCTION

49
50 Vegetation is strongly affected by environmental changes such as climate, biotic interactions
51 and human activities. Disentangling the role of these factors on vegetation changes, particularly
52 climate variability and human impact, is one of the major challenges in paleoenvironmental
53 research. Long paleoecological records in lake and mire sedimentary systems, including times
54 prior to human impact, are a valuable tool to decode community dynamics over time, which aids
55 in understanding the underlying ecological processes involved and how plants respond to
56 different factors.

57

58 The importance of climate and human actions on landscape changes is one of the main issues
59 discussed in the Pacific Islands and especially in Easter Island. Most of the work performed on
60 this tiny island has been focused on human settlement and its ecological impacts, especially
61 after earlier palynological work evinced a recent replacement of former palm-dominant forests
62 by grasslands. This replacement has been attributed to a rapid anthropic deforestation that led to
63 soil degradation, the overexploitation of natural resources and social collapse (e.g., Flenley et al.
64 1991; Flenley and Bahn 2003). Thus, the island has become one of the most popular examples
65 of dramatic environmental degradation wrought by humans, often being treated as a microcosm
66 of the Earth and a model of the potential consequences of current management practices at a
67 global scale. Although a potential role for recent climatic events in this deforestation, such as
68 the Little Ice Age (LIA) or an intensification of the ENSO variability, has also been proposed
69 (e.g., Hunter-Anderson 1998; McCall 1993, Nunn 2000), climate and other environmental
70 changes have been in many cases explicitly dismissed as drivers of this vegetation replacement
71 because these proposals were primarily based on theoretical speculations (Flenley and Bahn
72 2003; Rull et al. 2013). Nevertheless, the ~~climate role~~ idea has gained support with the latest
73 paleoecological studies that have revealed sedimentary gaps in the studied sequences due to arid
74 climate, notable hydrological changes and a gradual landscape transformation during the last
75 two thousand years rather than a sudden change as initially alleged (Cañellas-Boltà et al. 2013;
76 Sáez et al. 2009).

77

78 The vegetation dynamics in Easter Island is still far from being well understood as only a few
79 long vegetation records have been studied (Butler and Flenley 2010; Flenley et al. 1991;
80 Horrocks et al. 2012, 2013). These studies have provided significant data about the indigenous
81 flora and vegetation, but the vegetation's dynamics and response to gradual and abrupt climate
82 changes is still fairly unknown. The studies have shown forested vegetation in the island, with
83 palms, *Sophora*, Asteraceae and *Triumfetta* as the ~~main~~ dominant plants (Azizi and Flenley
84 2008; Flenley et al. 1991). A recent study performed on Raraku sediments has revealed the

85 ~~notable presence in the lake basin between 8.6 and 5.5 cal ka BP~~ of a now-extinct plant,
86 *Dianella* cf. *adenanthera/intermedia* (Cañellas-Boltà et al. 2014). Earlier paleoenvironmental
87 studies noted vegetation changes (deduced from pollen data) prior to ~~human arrival~~ due to
88 climate changes, but these climatic inferences were made simultaneously from the same pollen
89 data, which prevents an independent assessment of the climate changes occurring and the
90 vegetation responses to them (e.g., Flenley et al. 1991; Flenley and Bahn 2003). Moreover,
91 dating inconsistencies and sedimentary hiatuses complicate the interpretation (Rull et al. 2010)
92 of most of these records (e.g., Butler and Flenley 2001; Flenley et al. 1991, Horrocks et al.
93 2012, 2013). Further paleoenvironmental studies combining stratigraphy, sedimentological,
94 mineralogical and geochemical data have provided detailed reconstruction of the hydrological
95 evolution of two wetlands on the island (Raraku Lake ~~since~~ c. 34 cal ka BP and Rano Aroi ~~since~~
96 70 ka BP), allowing ~~for~~ inference of the climate history of the late Quaternary (Cañellas-Boltà et
97 al. 2012; Margalef et al. 2013, 2014; Sáez et al. 2009).

98
99 Here, we present a ~~long-term~~ multiproxy study of a composite sedimentary core obtained at
100 Raraku Lake, spanning from 34 to 4.3 cal ka BP, with the aim of studying vegetation dynamics
101 and its related environmental driving forces without being hampered by the impact of human
102 activities. In the present work, ~~pollen data at the highest resolution to date for this lake~~ have
103 been combined with data from previous studies ~~using~~ sedimentological, geochemical
104 (continuous x-ray fluorescence, bulk organic elemental and isotopic analyses) and macrofossil
105 ~~analyses of the same core~~ (Cañellas-Boltà et al. 2012; Sáez et al. 2009). Thus, this approach
106 allows us to compare biotic responses (vegetation changes deduced from pollen and macrofossil
107 data) to environmental changes (inferred from geochemical and sedimentological changes),
108 avoiding circular reasoning. Moreover, the integration of these different data can contribute to
109 the knowledge of favorable climatic conditions for species that are still not well known. This
110 integration is particularly important in Easter Island, where climatic interpretations have so far
111 been inferred from the potential autoecology of the species, which is unavoidably speculative in
112 unknown species and large families identified at only high taxonomical levels. The integration

113 of these results with previous work focused on the paleoecology of the last four millennia
114 (Cañellas-Boltà et al. 2013) provides a complete scenario for vegetation and environmental
115 changes in the Raraku Lake catchment since 34 cal ka BP. This study documents significant
116 (and sometimes rapid) vegetation changes prior to human impact due to climate variations and
117 sedimentary lacustrine processes.

118

119 2. STUDY SITE

120 Easter Island is a ~~tiny~~ (~164 Km²) and remote volcanic island located in the South Pacific
121 Ocean (27° 70'S-109° 220'W, fig. 1) at approximately 3700 km from the Chilean coast and
122 2030 km from the nearest inhabited island (Pitcairn). The island has a roughly triangular shape
123 formed by three  volcanoes in each corner. Mount Terevaka is the highest summit (511 m)
124 of the island (fig. 1). No permanent surface streams are present currently due to the high
125 permeability of the volcanic rocks (Herrera and Custodio 2008). The craters of Rano Raraku,
126 Rano Kau (occupied by lakes) and Rano Aroi (filled by a mire) are the three current, permanent
127 water reservoirs (fig.1). The native flora and fauna have been described as very poor owing to
128 the isolation and small area (Skottsberg 1956; Zizka 1991) and have been greatly altered by
129 human activities (Dubois et al. 2013; Zizka 1991). Currently, the island is mostly covered by
130 grasslands (90%), with a few tree plantations (mainly of *Eucalyptus* and *Melia azederach*),
131 shrublands areas and pioneer vegetation (CONAF 1997; Etienne et al. 1982). The grasslands are
132 ~~mainly~~ dominated by *Sporobolus indicus* and *Paspalum scrobiculatum*, with *Axonopus*
133 *paschalis* as a local dominant in the highest sectors of the Mount Terevaka. The shrublands are
134 largely dominated by the introduced *Psidium guajava*, jointly with *Crotalaria* sp. and *Lupinus*
135 *arboreus* among others (CONAF 1997).

136

137 The climate is subtropical, with average monthly temperatures that range between 16 °C (July-
138 September) and 26 °C (January-March). The total annual precipitation is highly variable,
139 oscillating between 500 and 2000 mm. Precipitation is mainly determined by the interplay of the
140 South Pacific Anticyclone (SPA), the Intertropical Convergence Zone (ITCZ), the South Pacific

141 Convergence Zone (SPCZ) and the Westerly storm tracks (SW) (Margalef et al. 2013; Sáez et
142 al. 2009). Higher rainfall rates occur in winter months owing to the weakness of the SPA and
143 the northward seasonal migration of the ITCZ, the SPCZ and the SW. During summer, rain is
144 mainly driven by the land-sea breeze and convection induced by warmer Sea Surface
145 Temperatures (SST) and Easter Island orography (Junk and Claussen 2011; Mucciarone and
146 Dunbar 2003). No correlation has been found between ENSO and rainfall on Easter Island
147 (Genz and Hunt 2003; MacIntyre 2001a, 2001b), although ENSO variability and dynamics are
148 responsible for changes in the SST and the predominant wind direction in the region (Anderson
149 et al. 2006; Mucciarone and Dunbar 2003).

150

151 Raraku Lake is a small (0.11 km²) shallow (2-3 m depth) freshwater lake (Sáez et al. 2009),
152 situated at 75 m above sea level inside a volcanic crater more than 300,000 years old (Baker et
153 al. 1974) (fig. 1). The catchment (≈ 0.35 km²) is mainly composed of volcanic tuff rich in glass,
154 feldspar, and ilmenite (González-Ferran et al. 2004). The lake is topographically and
155 hydrologically closed and disconnected from the island's main groundwater by impermeable
156 lacustrine sediments (Herrera and Custodio 2008). Rainfall and run-off are the only water
157 inputs. Currently, the lake has a flat bottom and is surrounded by a considerably wide littoral
158 belt mainly formed by *Scirpus californicus* and *Polygonum acuminatum*. Moreover, the sedge
159 *Scirpus californicus* (totora) also forms large floating patches of mat. The catchment is mainly
160 occupied by grasslands, with some introduced shrubs such as *Crotalaria* sp., *Psidium guayava*,
161 *Verbena littoralis* and *Lantana camara*.

162

163 3. MATERIAL AND METHODS

164 The material studied was a composite stratigraphic sequence of 19 m thick retrieved from
165 Raraku Lake, formed by cores RAR 03 and RAR 07 (fig. 2, see Sáez et al. 2009 for further
166 details). They were recovered in 2006 using an UWITEC corer installed in a floating raft (see
167 Sáez et al. 2009). The initial chronological framework was built using 25 radiocarbon dates
168 from pollen enriched-extracts and large stems of *Scirpus* (see Sáez et al. (2009) and Cañellas-

169 Boltà et al. (2012) for further details) (table 1). For the present paper, an improved age-depth
170 model and its uncertain ranges was constructed with Clam software (Blaauw 2010) using linear
171 interpolation between adjacent radiocarbon dates. Dates were calibrated using the South
172 Hemisphere calibration curve SHCal13 (Hogg et al. 2013). The uppermost ~40 cm of this
173 composite core, which contains approximately 4,000 years of the climate and environmental
174 history of Easter island, have not been included in this study due to inconsistencies in the
175 chronological framework, with long sedimentary hiatuses and age reversals. Instead, the main
176 vegetation and environmental trends for these last four millennia have been extracted from the
177 study of Cañellas-Boltà et al. (2013) performed on core RAR 08 of the Raraku Lake.

178

179 Ninety-seven samples of this composite core were prepared for pollen analysis. The samples
180 were spiked with *Lycopodium* tablets (batch 177745) and processed using slightly modified
181 standard laboratory procedures, which include sieving, KOH, HCl and HF digestions, and
182 acetolysis (Rull et al. 2010b). The slides were mounted in silicone oil for analysis by light-
183 microscopy at 400x magnification. Pollen counting was performed until at least 200 pollen
184 grains had been reached (pollen sum), excluding wetland taxa such as ~~Cyperaceae and~~
185 ~~Polygonum~~. In cases where pollen was very scarce, at least 300 exotic markers (*Lycopodium*
186 spores) have been counted. In samples with more than 200 pollen grains counted, the number of
187 exotic markers is always well below 300. The pollen diagrams were plotted using *psimpoll* 4.26
188 software (Bennett 2002), and statistically significant pollen zones were obtained using the
189 method of optimal splitting by information content (OSIC) (Bennett 1996).

190

191 A distance-based canonical redundancy analysis (db-RDA) (Legendre and Legendre 1998) was
192 carried on pollen data with geochemical and sedimentological parameters of the same composite
193 sequence already published in Cañellas-Boltà et al. (2012) and Sáez et al. (2009). These
194 parameters include the following: XRF data counts of Si, Ti, S, Fe, Ca; the Rayleigh incoherent
195 to Compton coherent x-ray fluorescence ratio (In.coh.ratio) as a proxy of organic matter;
196 magnetic susceptibility (MS); total nitrogen (TN), total carbon (TC), and their respective stable

197 isotopes ($\delta^{15}\text{N}$ and $\delta^{13}\text{C}$) from bulk organic matter; and the sedimentary facies association (table
198 2). This constrained ordination analysis allows us to graphically summarize the major patterns
199 of biological variation and their relationship with the environmental variables using ecologically
200 meaningful measures of community distance rather than the Euclidean distance. In the db-RDA,
201 sample scores from a Principal Coordinate Analysis (PcoA performed using Hellinger distance)
202 are used as the species data in a redundancy analysis (Legendre and Gallagher 2001). The
203 analysis was performed with R software (R Development Core Team 2015) and the *vegan*
204 package (Oksanen et al. 2006). Two samples with geochemical missing values (at 2.23 and
205 16.34 m depth) were removed. The rate-of-change, a quantitative estimate of change per unit
206 time (Bennett and Humpry 1995), was also calculated with *psimpoll* 4.26 software using chord
207 distance as a dissimilarity measure between samples. Other dissimilarity coefficients, such as
208 the Chi-squared coefficient, Euclidean distance, etc., yield similar results (not shown). To
209 compare the rate of these changes with those that occurred during the last four millennia, a rate
210 of change has also been computed from pollen data from core RAR 08 (Cañellas-Boltà et al.
211 2013) spanning the last 3.7 cal ka BP.

212

213 **4. RESULTS**

214

215 **4.1. Chronology.**

216 The age-depth model constructed for the composite sequence RAR 03/07 is shown in figure 2.
217 According to this model, the lake sequence records the last 34 cal ka BP. At 40 cm depth (c. 4.3
218 cal ka BP), a sedimentary hiatus spanning c. 4000 years has been identified by sedimentological
219 evidence. The sedimentation rate in the lower third of the sedimentary record is approximately
220 0.32 ± 0.03 mm/yr. With the onset of the deglaciation at c. 16.5 cal ka BP the sedimentation rate
221 increased and remained at approximately 1.16 mm/yr ± 0.61 until to ca. 9.3 cal ka BP. In the
222 upper third of the sedimentary record, the sedimentation rate is approximately 1.66 mm/yr \pm
223 0.85 .

224

225

226 4.2. Pollen analysis

227 The pollen results are depicted in figure 3. The palynological record is dominated by tree and
228 shrub pollen, except between 1.5 and 6 m depth, where herbs, mainly *Dianella*, replace them.
229 Palm pollen is the main type observed, together with intermediate values of *Sophora*,
230 *Triumfetta*, Poaceae and Asteraceae. From the bottom to the top, seven significant pollen zones
231 have been identified; they are summarized below.

232

233 - Pollen zone RAK-1 (9 samples; 19-18 m depth; 34.1 to 31.3 cal ka BP)

234 This zone is characterized by a high percentage of tree and shrub pollen. Palm pollen is the
235 dominant type (50-65%). The striking percentage of *Coprosma* sp. (~2-10%) is remarkable, as
236 are those of *Sophora*, *Triumfetta*, Asteraceae and Poaceae. Moraceae/*Trema*-type and cf.
237 *Sapindus* are relatively abundant through the zone; only a few scattered Myrtaceae and
238 Apiaceae are observed. Ferns show high diversity, although they are present in low percentages.
239 The most abundant ferns are *Pteris* and foveolate and scabrate trilete spore types. In addition,
240 little Cyperaceae pollen is recorded.

241

242 - Pollen zone RAK-2 (43 samples; 18-13.45 m depth; 31.3 to 16.8 cal ka BP)

243 A slight increase in herb pollen is observed in this zone. Palm pollen percentage slightly
244 decreases (30-55%), but it still dominates the record. *Triumfetta* also shows a reduction,
245 together with *Coprosma*, which almost disappears and is only sporadically present in a few
246 samples. In contrast, the proportions of *Sophora*, Poaceae and Asteraceae undergo a marked
247 increase, particularly at the upper part of the zone. Moraceae/*Trema*-type and cf. *Sapindus*
248 continue to be present in low percentage, whereas some Myrtaceae sp. and Apiaceae sp. are
249 observed scattered in several samples. Likewise, Cyperaceae pollen and fern spores remain in
250 low percentage. The continued high diversity of fern spores is noteworthy, with a slight increase
251 in foveolate trilete and aerolate monolet spores in the upper half of the zone. Trilete echinate
252 spores are confined from 14.5 to 16 m depth.

253

254 **- Pollen zone RAK-3 (19 samples; 13.45-8.2 m depth; 16.8 to 10.9 cal ka BP)**

255 In general, the samples of this zone have low pollen content and preservation; in fact, some of
256 ~~them do not reach~~ 200 pollen grains ~~counted~~. A marked increase in palm (reaching values
257 approximately 70-80%) and *Triumfetta* pollen percentages characterizes the zone. In contrast,
258 *Sophora*, Poaceae and Asteraceae notably decrease. Likewise, Moraceae/*Trema*-type and cf.
259 *Sapindus*, sharply decline and are only sporadically observed in very few samples. Ferns spores
260 also decrease and some types disappear. Only *Pteris*-type is relatively abundant, and aerolate
261 and psilate monolete spores show low percentage values. Foveolate trilete and echinate
262 monolete fern spores are observed in only the bottom of the zone. An interval of higher *Sophora*
263 and lower Poaceae between 11.5 to 10.2 m depth is recognized. Above 11 m depth, Cyperaceae
264 pollen notably increases, coinciding with the enhanced drop in Asteraceae. Another outstanding
265 characteristic of the zone is the presence of abundant algal microremains (cf. *Tetraedrum*).

266

267 **- Pollen zone RAK-4 (7 samples; 8.2-6 m depth; 10.9-8.6 cal ka BP)**

268 The pollen zone RAK-4 is dominated by palms, reaching values of 80-90%. In contrast,
269 *Triumfetta*, Poaceae and Asteraceae undergo a remarkable decrease, and the latter one
270 disappears at the upper half of the zone. On another hand, fern spores show a great increase,
271 mainly in the scabrate and psilate monolete types. However, *Pteris*-type disappears from the
272 record. Cyperaceae pollen percentage shows a progressive increasing trend through the zone.
273 The appearance of *Dianella* sp. in the upper half of the zone is also noteworthy.

274

275 **- Pollen zone RAK-5 (4 samples; 6-4.8 m depth; 8.6-7.8 cal ka BP)**

276 This small zone is characterized by an abrupt and conspicuous change in the pollen
277 assemblages. A steep increase in pteridophyte spores, mainly monolete types, is observed,
278 reaching a pronounced peak at the top of the zone together with a steady dramatic increase in
279 *Dianella* pollen. Hence, herb pollen became dominant at the expense of palm, which shows a
280 marked decrease in percentage (the lowest values in the sequence). *Triumfetta* pollen percentage

281 ~~also diminishes.~~ On another hand, Cyperaceae pollen is abundant, although a slight decreasing
282 trend within the zone is observed.

283

284 **- Pollen zone RAK-6 (10 samples; 4.8-1.7 m depth; 7.8-5.5 cal ka BP)**

285 The pollen zone RAK-6 is distinguished by the dominance of herbs, mainly *Dianella*. However,
286 this pollen type shows a gradual decreasing trend through the zone. Peridophyte spores undergo
287 a sudden and sharp decline and almost disappear from the record. In contrast, Poaceae pollen
288 shows low percentage values at the beginning of the zone but increases from 3.5 m depth up to
289 the top. Palm pollen presents intermediate percentage values, whereas *Sophora* and *Triumfetta*
290 show low values. On the other hand, Cyperaceae pollen is also abundant and shows a notable
291 gradual increase from 3.5 m depth to the top of the zone. This roughly coincides with the
292 increase in Poaceae and *Canavalia* and the appearance of *Polygonum* in the record.

293

294 **-Pollen zone RAK-7 (5 samples; 1.7-0.4 m depth; 5.5- 4.3 cal ka BP)**

295 This zone is characterized by a marked rise in palm and Cyperaceae pollen. The ~~steep~~ increase
296 in palm pollen reaches values of 80% ~~of the pollen sum~~ and is accompanied by a notable rise in
297 Asteraceae and *Triumfetta*. In contrast, *Dianella* abruptly declines and disappears from the
298 record. Poaceae pollen also decreases. At the top of the zone (first few centimeters), increases in
299 *Sophora*, *Canavalia*, *Polygonum* and monolete spores are observed, jointly with a decrease in
300 Cyperaceae.

301

302 **4.2. Multivariate analyses and rate of vegetation change**

303 The results of db-RDA analysis are depicted in figure 4. The two first axes account for 54% of
304 the total variance. Notable relationships between pollen content and sedimentological and
305 geochemical parameters are observed (fig. 4). The pollen zones RAK-1/RAK-2 are strongly tied
306 to large terrigenous inputs (identified by high values of magnetic susceptibility [MS], Fe, and
307 Ti), high values of $\delta^{13}\text{C}$, Si, S, and a silty facies identified as High Gradient Lake (HGL). In
308 contrast, the zones RAK-3 and RAK-4 are ~~roughly~~ related to Low Gradient Lake (LGL) ~~muddy~~

309 facies and higher TN and TC values. On the other hand, samples from pollen zones RAK-5 and
310 RAK-6 correlate to ~~swamp~~ peaty facies (SWA) and high $\delta^{15}\text{N}$ values. Finally, samples of the
311 zone RAK-7 are tied to higher total carbon and total nitrogen values and seem to correspond to
312 the transition from peat ~~swampy~~ facies to silty peat low gradient lake facies ~~associations~~.

313

314 Regarding rate of change, high values are observed during the early-mid Holocene, between 9.5
315 and 4.3 cal ka BP, with maxima between 9 and 7 cal ka BP (figure 5). Comparison of these
316 values with the rate of change during last four millennia shows that they are similar to those
317 occurring during 700-200 cal years BP. In the last two centuries, however, the rate of vegetation
318 change is particularly high. Another period with relatively higher values of rate of change is
319 recognized between 13-11 cal ka BP.

320

321 **5. Interpretation and discussion**

322 **5.1. Vegetation dynamics at Raraku Lake catchment**

323 The pollen record reveals notable vegetation changes in the last 34 cal ka BP (fig. 5). The most
324 conspicuous change in vegetation composition occurred with the transformation of the Raraku
325 Lake into a mire in the early Holocene. This terrestrialization implied an outstanding increase of
326 herbaceous taxa (fig. 5) represented by axis 1 of the db-RDA (41.13% of the total variability,
327 fig. 4). Hereafter, the vegetation patterns observed are detailed in their climate context.

328

329 **- 34.1 to 31.3 cal ka BP (RAK-1; Last Glacial)**

330 According to the pollen record, forested vegetation, mainly dominated by palms, grew in the
331 catchment during the Last Glacial. The ~~notable~~ abundance of Poaceae and ferns shows that the
332 vegetation canopy was relatively open. Therefore, we interpret that the lake was surrounded by
333 an open mixed forest, with palms and *Sophora* dominant, jointly with *Coprosma*, *Triumfetta*
334 and other elements forming a diverse understory (fig. 5 and 6). Sedimentary and geochemical
335 data suggested cold and relatively humid climate conditions and a high lake level during the
336 Last Glacial Period (Sáez et al. 2009). These conditions, together with the steep slopes of the

337 relatively deep lake identified during this period, contributed to prevent the development of
338 littoral vegetation, as suggested by the low abundance of Cyperaceae pollen and wetland plants.
339 South American marine records have indicated relatively dry conditions between 30 and 40 cal.
340 ka BP at mid latitudes (Lamy et al. 1998; Stuut and Lamy 2004) caused by the poleward
341 position of the Southern Westerlies during the precession maximum (Kaiser et al. 2008; Lamy
342 et al. 1998; Stuut and Lamy 2004). The geochemical composition of Raraku Lake sediments
343 does not record these relatively dry conditions, ~~might be because convective storms were still~~
344 ~~occurring at the island due to the island effect (Cronin et al. 2014; Junk and Claussen 2011).~~
345 ~~This substantial rainfall coupled with the low evaporation caused by these global cold~~
346 ~~conditions would have been responsible for the interpreted relatively high water level (Sáez et~~
347 ~~al. 2009).~~ However, a brief dry episode at some point between 39-31 cal ka BP has been
348 suggested by the nearby record of Rano Aroi, located at higher altitude (430 m asl) in Easter
349 Island (Margalef et al. 2013, 2014). Rano Aroi may be more sensitive to moisture changes
350 because it lies on an extremely permeable substrate and its location coincides with the
351 uppermost limit of the perched spring phreatic level (Margalef et al. 2013, 2014).

352

353 - 31.3 to 16.8 cal ka BP (RAK-2; Last Glacial)

354 Between 31.3 and 16.8 cal ka BP, the palm grove underwent a little increase in openness, as
355 shown by a small rise in Poaceae concomitant with a slight drop in *Triumfetta* and palms.
356 Notable features of this period is the abrupt decline in *Coprosma* and the increasing presence of
357 the small tree-shrub *Sophora* (fig. 5 and 6). This vegetation change coincides with a slight
358 increase in the frequency of flood events and terrigenous delivery inputs (higher Ti, Fe, and MS
359 values), interpreted as a period with more abundant and intense precipitation also in the
360 highstand phase (Sáez et al. 2009). This paleoclimatic interpretation contrasts with earlier works
361 on the island that described a cold and dry Last Glacial period (Azizi and Flenley 2008; Flenley
362 et al. 1991). However, regional paleoclimatic evidence at mid-latitudes offshore and on the west
363 coast of South America are in accordance with our interpretation. The coolest temperatures and
364 very humid conditions were described between 30 and 19 ka BP on marine cores at 30°S-32°S

365 (Kaiser et al. 2008; Kim et al. 2002; Kohfeld et al. 2013; Stuut and Lamy 2004). These climatic
366 conditions lead to a maximum of Poaceae and a minimum of *Triumfetta* and palms in the
367 Raraku catchment. The precipitation increases at these latitudes have been associated with the
368 southward migration of the ITCZ and the northward displacement or strengthening of the
369 Southern Westerlies (Kaiser et al. 2008; Kohfeld et al. 2013). Moreover, paleoclimatic models
370 and several records also indicate an El Niño-like configuration in the South Pacific that could
371 also contribute to explaining the wetter conditions over the Central Pacific (Koutavas et al.
372 2002; Stott et al. 2002).

373

374 - c. 16.8 to 10.9 cal ka BP (RAK-3; Late Glacial –Termination 1)

375 At 16.8 cal ka BP, the notable increase in palms and *Triumfetta* at the expense of other shrubs,
376 herbs and some ferns suggests that the palm grove at the lake surroundings probably became
377 less diverse and more closed (figure 5 and 6). This substantial vegetation change characterized
378 the start of the warmer and drier period of deglaciation identified on Easter Island at c. 17 cal ka
379 BP in the geochemical and sedimentary records from both the Raraku Lake and the Aroi mire
380 sequences (Margalef et al. 2013, 2014, Sáez et al. 2009). At Raraku Lake, Sáez et al. (2009)
381 recognized a significant lake level drop at c.17 cal ka BP and shallow lake conditions with the
382 development of a low-gradient lake (LGL) facies until c. 9 ka BP. The increase in the
383 Cyperaceae record suggests the increasing occupancy of emergent vegetation, probably forming
384 a littoral belt surrounding the lake, ~~permitted by the lower lake levels and less steep slopes~~
385 ~~present during this period.~~ Nevertheless, these vegetation interpretations deduced from the
386 pollen record should be taken with caution due to the low number of pollen grains present in
387 most of the samples from this period, which could distort some trends. Moreover, many of the
388 pollen grains observed were degraded, which suggest some aerobic exposure of the sediment.
389 Episodes of aerial exposition in shallow lakes are common and could be one of the reasons for
390 the scarcity of the pollen. Furthermore, the noteworthy abundance of *Tetraedrum* algae
391 microremains, particularly between c. 13 to c. 9.5 cal ka BP, implies eutrophic conditions for
392 the shallow Raraku Lake. These data corroborate the enhanced lake productivity from algal

393 origin suggested by sedimentological evidence and the increases of TC and TN (fig. 5) (Sáez et
394 al. 2009). Eutrophication was probably produced by the lowering of the lake level facilitating
395 nutrient availability and/or from washed-in nutrients as a result of increased erosion of new
396 exposed lake margins. In fact, at the beginning of this period, two major coarse-grained layers
397 were identified, suggesting high erosion from the catchment by lowstand lake conditions (Sáez
398 et al. 2009).

399

400 Most of the mid-litudinal continental circum-South Pacific records agree with the onset of
401 deglaciation at c. 17 cal ka BP, although marine records suggest an early warming (Bertrand et
402 al. 2008; Montade et al. 2013; Stern et al. 2014). Regarding this finding, overall marine records
403 from the central Pacific region show warming started at 19 cal ka BP, whereas a ~~humidity~~
404 decrease occurred approximately 17-16 ka BP (Kaiser et al. 2008; Kim et al. 2002). Parallel to
405 the warming, the Southern Patagonia and New Zealand glaciers started to retreat (Murray et al.
406 2012). The warmer and drier conditions suggested in low latitudes of the east Pacific has been
407 related to phases of low precession and high obliquity (Pena et al. 2008), which drove storm
408 tracks southward and enhanced the E-W Pacific thermal gradient, favoring La Niña-like
409 conditions (Koutavas et al. 2002; Pena et al. 2008).

410

411 Interestingly, our pollen record indicates a slight vegetation change between c.13.2 -11.8 cal ka
412 BP with increased presence of *Sophora* and ~~an enhanced drop~~ of Asteraceae and Poaceae, ~~which~~
413 can be related to the Younger Dryas chron (YD: 12.8 to 11.5 cal ka BP). Both geochemical and
414 sedimentary records suggest increased climate variability, pointing to moisture increases,
415 recorded ~~as a remarkable~~ oscillation in TC, C/N and $\delta^{13}\text{C}$ values. The global occurrence of the
416 YD event, an interval of abrupt cold reversal primarily described at the Northern Hemisphere, is
417 in debate. It has been identified in several Southern hemispheric paleoclimatic records,
418 generally as a wet interval (e.g., Bertrand et al. 2008; Glasser et al. 2012; Mayr et al. 2013) but
419 was missing in many others (e.g., Hillyer et al. 2009; Kilian and Lamy 2012).

420

421 - 10.9 to 8.6 cal ka BP (RAK IV; early Holocene)

422 In the early Holocene, the drop in *Triumfetta*, Asteraceae and Poaceae suggests that a palm
423 grove with a poorly developed understory dominated the Raraku basin (between 10.9 and 8.6
424 cal ka BP) (fig. 5 and 6). The increase in Cyperaceae and ferns reflects the continued expansion
425 of the littoral vegetation belt surrounding the lake. At c. 9 cal ka BP, the disappearance of the
426 algae *Tetraedrum* suggests a complete terrestrialization into a mire. These shifts co-occur with
427 changes in the sedimentary record such as the transition of muddy sediment into a muddy peat
428 (and shortly afterwards into a peat) and the increase in C/N ratio (Sáez et al. 2009). The pollen
429 data show that sedges and ferns were the first to colonize water-saturated lands of the mire
430 (upper half of RAK-IV, fig. 5 and 6), probably extending from the shores. Macrofossil data
431 (Cañellas-Boltà et al. 2012) note that the main sedge was *Scirpus* cf. *californicus*, a tall
432 emergent plant (of more than 2 m) that can live in flooded environments as in all the
433 waterbodies of the island at present (Dubois et al. 2013; Zizka 1991) and invades sites with low
434 water level. Likewise, ferns are often pioneer plants on perturbed or new open sites, thanks to
435 their capability of rapid establishment and growth, commonly forming thickets by vegetative
436 expansion (Mehltreter et al. 2010). This group usually grows on moist environments (Mehltreter
437 et al. 2010) and could have grown in the external lake margins. Drier conditions or lowering
438 waters by progressive matter accumulation, perhaps facilitated by the presence of Cyperaceae,
439 could enable their spread.

440

441 From a regional perspective, arid and warmer conditions during the early-mid Holocene were
442 suggested from many mid-latitude South American records (e.g., Carré et al. 2011; Kaiser et
443 al. 2008; Lamy and De Pol-Holz 2013; Maldonado and Villagrán 2006; Valero-Garcés et al.
444 2005) and lasted until approximately 5-4 cal ka BP. These drier conditions have been linked to
445 stronger influence of the Southeast Pacific high-pressure cells, blocking westerly frontal
446 systems farther south, a weak or no ENSO activity, or La Niña-conditions (Carré et al. 2011;
447 Conroy et al. 2008; Maldonado-Villagrán 2002; Villa-Martínez et al. 2003).

448

449 - 8.6 to 7.8 cal ka BP (RAK-V; early-mid Holocene)

450 During the early-mid Holocene, a plant succession occurred in the Raraku mire, whereas the
451 palm grove continued to grow in the surroundings. From 8.6 to 7.8 cal ka BP a dramatic
452 increase in *Dianella* and ferns suggests that mire vegetation became rapidly dominated by these
453 plants, in combination with Cyperaceae. The microfossil data indicate the substitution of tall
454 *Scirpus* by *Cyperus* sp., which coincides with the highest C/N values, and hence probably a
455 lower water table in the mire.

456

457 - 7.8 to 5.5 cal ka BP (RAK-VI; mid Holocene)

458 At c. 7.8 cal ka BP, ferns abruptly declined and *Dianella* sp. ~~clearly~~ dominated the local
459 vegetation. The presence of *Dianella* progressively declined and Cyperaceae became more
460 abundant at c. 7 cal ka BP, probably due to the start of wetter conditions ~~on the island.~~

461 ~~Regarding this, a clear~~ wet episode has been identified in Raraku sediments as well as in Rano
462 Aroi, between 6-5.6 cal ka BP (Margalef et al. 2013; Sáez et al. 2009). A similar wet episode at
463 the same time was also observed in the Galapagos Islands (6-5.8 cal ka BP, Conroy et al. 2008)
464 and globally (Mayewski et al. 2004), coinciding with stronger SW activity in Southern Chile
465 (Heirman, 2011). This episode (at 5.6 cal ka BP) also coincides with a rhyolitic volcanic
466 eruption at New Zealand, the Haroharo volcanic complex, which emitted a huge amount of
467 ashes and pyroclastic material that could have affected climate in the Pacific Region (Holt et al.
468 2011; Kobayashi et al. 2010).

469

470 - 5.5 to 4.3 cal ka BP (RAK VII; mid-Holocene)

471 At 5.5 cal ka BP, Cyperaceae dominated the wetland vegetation again (5.5 to 4.3 cal ka BP).
472 Microfossils indicate the replacement of *Cyperus*-type ~~seed dominance~~ by *Scirpus* ~~seeds~~ at that
473 time, a conspicuous decrease in zoological remains (oribatid mites and weevils) and the
474 presence of some cladoceran ~~ephippia~~ (Cañellas-Boltà et al. 2012, 2014) (figure 5). All these
475 changes and the presence of *Tetraedrum* suggest a ~~likely~~ progressive rise in the water level in
476 the Raraku mire and wetter conditions after c. 5.5 cal ka BP, as suggested by the geochemical

477 record (high MS values, low C/N ratio and $\delta^{13}\text{C}$ values). Regionally, humid conditions started at
478 6-4 cal ka BP, as has been inferred from several mid-latitude South American records
479 (Moreno and León 2003; Valero-Garcés et al. 2005), related to an overall intensification of
480 ENSO conditions (e.g., Conroy et al. 2008; Maldonado and Villagrán 2006).

481

482 - 4.3 cal ka BP to present (Late Holocene)

483 In this section, we summarize the Late Holocene part of the Raraku record from the onshore
484 core RAR 08 (Cañellas-Boltà et al. 2013), which contains the most detailed record of the last
485 3700 years to date because it was affected by smaller stratigraphic gaps than the record depicted
486 ~~by RAR 03/07~~. The pollen diagram shows long and gradual-stepped landscape change at
487 Raraku basin, culminating in the replacement of the palm grove by grasslands (fig. 5). The
488 decline of palms and the expansion of herbs, mainly grasses, started at c. 450 BC and lasted
489 approximately two thousand years (fig. 5). The presence of *Verbena litoralis*, a ruderal weed,
490 suggests a human role in this change. Two sedimentary gaps in the record (c. AD 500 to c. AD
491 1200 and c. AD 1570 to AD 1720) are interpreted as periods of drought occurring during the
492 Medieval Climate Anomaly and the Little Ice Age, respectively, and may have also contributed
493 to the demise of palms (fig. 5). At c. AD 1200, the water table rose and the former Raraku mire
494 turned into a shallow lake, driven by the cooler and wetter Pan-Pacific AD 1300 event (Nunn
495 2007). Soon after AD 1200, palm deforestation accelerated and vegetation became dominated
496 by herbs. At c. AD 1875, *Verbena* decreased, giving way to the dominance of Poaceae. During
497 the last two centuries, the pollen record of RAR 08 shows the influence of human activities,
498 with the introduction of several taxa (e.g., *Psidium guajava*, *Eucalyptus* sp.) and the
499 disappearance of indigenous plants such as *Sophora toromiro*. Another study has identified
500 microfossils of introduced crops such as *Colocasia esculenta* (taro), *Ipomoea batatas* (sweet
501 potato), *Musa* (banana sp.) and possibly *Lagenaria siceraria* (bottle gourd), providing evidence
502 of ancient Polynesian agriculture in the lake surroundings by at least 627-513 cal years BP
503 (Horrocks et al. 2012).

504

505 5.2. Driving forces and rate of vegetation changes at Raraku crater

506

507 The vegetation dynamics at Raraku crater basin since the Last Glacial reflects a history of
508 interactions and synergies of different environmental factors. Some rapid vegetation changes
509 related to non-human environmental factors have been observed from 34 to 4.3 cal ka BP, as
510 shown by the significant relationships (db-RDA results) between palynological changes and
511 sedimentological and geochemical data interpreted as hydrological and climatic proxies.
512 Precipitation and temperature variations triggered community composition changes in terms of
513 species presence and abundance. Regarding these changes, the transition from a relatively open
514 and diverse palm grove to an increasingly palm-dominated forest with a poorer understory
515 during deglaciation represents a ~~clear~~, rapid and conspicuous vegetation response to climate
516 ~~variation~~. Warmer and/or drier conditions ~~clearly~~ favored the expansion of palms and *Triumfetta*
517 at the expense of Asteraceae and *Sophora*, among others. Similarly, our data reveal that the
518 wetter and/or cooler conditions between 31.3 and 16.8 cal ka BP promoted the increase of
519 grasses and *Sophora*. ~~These~~ conditions probably contributed to the dramatic decline of
520 *Coprosma* at 31.1 cal ka BP, when it practically disappears from the record. ~~This genus is~~
521 ~~widely distributed in the Pacific, with abundant endemic species,~~ and occupies a broad range of
522 habitats (Cantley et al. 2014). Nevertheless, the abrupt demise of *Coprosma* ~~at 31.3 cal ka BP~~ is
523 difficult to explain by ~~only~~ the small climate changes recognized in the Raraku record. The
524 punctuated drought occurred at that time (recorded in  ~~the pollen~~
525 ~~highly~~ have damaged this plant and affect its ability to compete with others, such as *Sophora*.
526 However, other non-climatic factors, such as biotic interactions like predation, disease, etc., or a
527 combination of causes, could have also been involved.

528

529 In addition to the synergistic interplays with climate, the depositional processes in the basin
530 have also significantly mediated vegetation changes. In this sense, the lake infilling processes
531 contribute to the ~~lake level~~ shallowing trend, which facilitates the development of a mire system
532 and the expansion of emergent vegetation under the warmer and drier climate of the early

533 Holocene (fig. 5 and 6). This culminated in the encroachment of the crater by vegetation and the
534 transformation of the shallow lake into a mire. The plant succession occurring during the mire
535 establishment was one the most important and rapid vegetation change of the last 34,000 years
536 in the vegetation in Raraku Lake basin (fig 5). The db-RDA results clearly distinguish pollen
537 assemblages from lake and mire environments (figure 4). Mire deposits show less diversity,
538 basically recording herbs, emergent plants (such as Cyperaceae) or vegetation linked to moist
539 habitat (such as ferns). The presence of peat-forming vegetation and in-situ accumulation is
540 corroborated by the macrofossil record in Raraku Lake (Cañellas-Boltà et al., 2012). The
541 ecological and depositional characteristics of the mire system explain the strong local signal of
542 the pollen as the mire is more shielded from external material inputs than the previous lake
543 system. Samples from sediments accumulated in the lake environment show higher taxonomic
544 diversity, mainly of trees and shrubs, which are not usually present in the macrofossil record.
545 Therefore, the pollen record of the mire could partly obscure some vegetation patterns in the
546 catchment during the Holocene due to its more local imprint. This strengthens the importance of
547 understanding the lake evolution history in the interpretation of the record.

548

549 The ecological thresholds of plants growing in the mire, and their capabilities of colonization,
550 establishment and competence played an increasingly relevant role in the relatively rapid
551 stepwise species turnover in the succession colonizing the mire (from phase IV to VII);
552 however, they are at the same time constrained by climate. Inherent succession processes
553 (autogenic mechanisms) likely intervened in the hydroseral succession. For example, peat
554 accumulation probably contributed to the decrease of water level in the lake, which likely
555 enabled the invasion of open water by emergent plants at the initial phases of terrestrialization
556 (threshold). These plants helped at the same time to accumulate peat and trap sediment,
557 contributing to the progressive lowering of the water table and aiding the invasion by others.
558 This process facilitated the spread of ferns, *Dianella* and small Cyperaceae at the expense of
559 *Scirpus*. The high competitive capability of *Dianella* during warm and/or dry climate conditions
560 could have been a decisive factor that led them to thrive, replacing fern dominance.

561 Nevertheless, this process was also mediated by climate. In this sense, the return to dominance
562 of *Scirpus* replacing *Dianella* coincides with increases in regional wet conditions, reflecting that
563 climate is an allogenic factor that also controls plant succession. The importance of hydrological
564 conditions (mainly consequent to climate) in hydrosereal succession has been demonstrated in
565 many works (e.g., Konning 2005; Ireland et al. 2012; Svitok et al. 2011).

566

567 Our data demonstrate that climate variations, as well as changes in the depositional
568 environment, have triggered dramatic and rapid vegetation shifts between 34 to 4.3 cal ka BP.
569 Therefore, it is plausible to conclude that vegetation changes during historical times have also
570 answered to synergies of climatic effects and human actions. Among the noteworthy anthropic
571 impacts on vegetation identified are plant extirpations, the introduction of allochthonous
572 vegetation and, especially, deforestation of the palm grove (Cañellas-Boltà, et al. 2013; Flenley
573 et al. 1991; Horrocks et al. 2012; Mann et al. 2008). However, the role of climate in these
574 vegetation changes cannot be ignored because it could have influenced vegetation changes or
575 enhanced the effect of human activities. For example, the intense drought episodes of the late
576 Holocene responsible for the sediment hiatus (Mann et al. 2008; Sáez et al. 2009) may have
577 weakened or damaged several plant species and contributed to the deforestation. Likewise,
578 cooler and wetter conditions, inferred from Raraku sediments around AD 1200 and roughly
579 coinciding with the acceleration of the palm decline, may have contributed to palm demise as
580 has been observed during the cooler and wetter conditions of the Late Glacial.

581

582 Comparisons of the rate of change of pollen data from human and non-human periods (fig. 5)
583 show similar magnitudes. In particular, very similar rates are observed at the onset of intense
584 human presence and at the first stages of hydrosereal succession at the beginning of the
585 Holocene. Another period with high change rate occurred between 12.5 and 11.8 cal ka BP,
586 with changes possibly related to climate instability during the YD. In the last centuries the rate
587 of change largely increased. ~~Although the estimates of rate of change are critically dependent on~~
588 ~~chronology (Birks 2012; Birks et al. 2010; Seppä and Bennett 2003) and hence could be~~

589 ~~affected by the different time intervals between contiguous samples, the~~ similar values of
590 climate- and human-induced transitions shown in this study emphasize the important influence
591 of non-human factors in the vegetation shifts. Therefore, the results suggest an important role of
592 climate and other factors in vegetation changes and in the ecological history of the island and
593 hence imply that their significance cannot be downplayed during the period of human
594 occupancy.

595

596 Our results support a moisture and temperature dependence for vegetation on the island.
597 Previous studies carried out in Rano Raraku, site (Azizi and Flenley 2008; Flenley et al. 1991)
598 mainly interpreted variations in palm abundances as temperature changes, proposing a scenario
599 of an island covered by palm forest in the lowlands with an altitudinal forest limit
600 approximately 450 m. According to these studies, the changes in the abundances of palms and
601 forest taxa reflected displacements of this treeline due to temperature changes. Rull et al. (2010)
602 indicated that other scenarios were compatible with available pollen data, such as a mosaic of
603 vegetation with a palm gallery forest around the wetlands. Our results show that both moisture
604 and temperature changes have brought major vegetation shifts, with significant variations in the
605 palms. Likewise, increased ferns have been usually interpreted as an indicator of wet conditions
606 (Flenley et al. 1991). In contrast, our results show that lake level drop played a key role in the
607 increase of ferns in the Raraku basin, contributing to the establishment of a shallow lake and
608 afterwards of the mire, providing new land for the spreading of these plants and a more local
609 record of vegetation.

610

611 **6. Conclusions and final remarks**

612 This paper reports the vegetation dynamics in the Raraku Lake during the late Quaternary
613 (between 34 and 4.3 cal ka BP), a period preceding the human presence on the island. The
614 vegetation changes recognized largely agree with the hydrological evolution and climate history
615 of the lake described previously for the same period and are coherent with regional
616 paleoclimatic records, indicating that climate is one of the main drivers of vegetation changes.

617 Moreover, the study provides strong evidence of the significant role in vegetation changes of the
618 interplay between climate variability, lake morphology changes and ecological thresholds and
619 feedbacks. These factors may provoke vegetation changes as important as the anthropogenic
620 ones and should be taken into account to understand vegetation history. Therefore, the
621 contribution of non-human factors in vegetation changes during historical times cannot be ruled
622 out. This is particularly important in Easter Island, where most of the paleoecological studies
623 have so far focused in the role of human activities in the demise of the alleged palm forest
624 present in the island, without assessing other possible agents. Moreover, the study illustrates the
625 usefulness of long paleoecological records to identify rapid vegetation changes and refuse the
626 use of a simple vegetation disruption as a proxy of human presence, which is common in the
627 study of Polynesian islands.

628

629 **Acknowledgements**

630 This research was funded by the Spanish Ministry of Science and Education through the
631 projects LAVOLTER (CGL2004-00683/BTE), GEOBILA (CGL2007-60932/BTE),
632 CONSOLIDER GRACCIE (CSD2007-00067) and RapidNAO (CGL2014-40608R) and an
633 undergraduate grant (BES-2008-002938 to N. Cañellas-Boltà). We gratefully acknowledge
634 CONAF (Chile) and the Riroroko family for the facilities provided on Easter Island.

For discussion of the inconsistency of several radiocarbon ages obtained see Sáez et al. 2009.

Table 2. Facies associations of Cañellas-Boltà et al. 2012 used in this study, their descriptions, and correspondence with facies and units described by Sáez et al. (2009).

FIGURE CAPTIONS

Figure 1. a) Map of Easter Island showing the location of Raraku Lake (Rano Raraku in local language). c) Location of Easter Island on a southern Pacific Ocean rainfall rate map (mm/yr) and main atmospheric systems. Modified from Sáez et al. (2009).

Figure 2. Age-depth model of composite core RAR 03/07. The lithostratigraphy of the composite core and radiocarbon dates are indicated at left.

Figure 3. Percentage diagram of the main pollen and spore types observed in Lake Raraku sequence. Pollen and spore percentages are based on pollen sum (excluding spores and emergent plants). Lithostratigraphy and AMS ^{14}C radiocarbon dates are indicated on the left of the diagram and calibrated dates on the right.

Figure 4. First two axes of distance-based Redundancy Analysis (db-RDA) of pollen assemblages and geochemical and sedimentary data. Pollen zones are indicated. The arrow indicates the main direction of dynamic through time.

Figure 5. Summary diagram of main pollen data (this study) together with some macrofossil (in bars) (Cañellas-Boltà et al. 2012) and geochemical (Sáez et al. 2009) data plotted in age. Upper c. 4 cal ka BP data from core RAR 08 (Cañellas-Boltà et al. 2013). Pollen and macrofossil zones and sedimentary facies are indicated. The rates of change between pollen samples are shown at right. White spaces represent sedimentary gaps. The combined alkenone-derived SSTs from cores GIK 17748-2 and GeoB 3302-1 at 32-33°S (Kim et al. 2002) and the humidity index inferred from core GeoB 3375-1 at 27°S (Stuut and Lamy 2004) are depicted at right. Time interval corresponding to the Younger Dryas is indicated. Facies abbreviations: HGL (High gradient lake), LGL (low gradient lake), SWA (swamp/mire), LFP (low gradient lake with floating peat mats).

Figure 6.1 Schematic drawing of main vegetation and lake level phases at Raraku crater catchment between 34 to 4.3 cal ka BP. Drawing is not to scale.

Table 1

Laboratory name	Composite depth (m)	Fraction dated	¹⁴ C yr BP	Date (cal ka BP)
Poz-20530	0.17	<i>Scirpus</i> macrorest	109 ± 0.4 pMC* ^a	
Poz-19934	0.20	Pollen-enriched extract	3205 ± 30 ^b	3396 ± 70.5
Poz-24023	0.3	<i>Scirpus</i> macrorest	112 ± 0.4 pMC* ^a	
Poz-33774	0.54	Pollen-enriched extract	4080 ± 40	4522.5 ± 106.5
Poz-24024	0.80	<i>Scirpus</i> macrorest	100 ± 0.4 pMC* ^a	
Poz-33775	1.28	Pollen-enriched extract	4670 ± 40	5378.5 ± 94.5
Poz-24025	1.55	<i>Scirpus</i> macrorest	490 ± 35 ^a	499 ± 42
Poz-20571	1.85	<i>Scirpus</i> macrorest	5030 ± 40	5686.5 ± 80.5
Poz-19935	2.30	Pollen-enriched extract	5450 ± 40	6235 ± 62
Poz-24026	2.85	<i>Scirpus</i> macrorest	3640 ± 35 ^b	3909 ± 83
Poz-24027	3.55	<i>Scirpus</i> macrorest	6170 ± 40	7030 ± 130
Poz-24030	4.14	<i>Scirpus</i> macrorest	6620 ± 50	7496 ± 74
Poz-18689	4.65	Pollen-enriched extract	6960 ± 40	7757.5 ± 91.5
Poz-24031	5.34	<i>Scirpus</i> macrorests	7410 ± 50	8182 ± 142
Poz-24032	6.15	<i>Scirpus</i> macrorests	7930 ± 50	8698.5 ± 114.5
Poz-18690	6.83	Pollen-enriched extract	8010 ± 40	8843.5 ± 150.5
Poz-18691	7.33	Pollen-enriched extract	8340 ± 50	9288.5 ± 159.5
Poz-19936	8.35	Pollen-enriched extract	9810 ± 60	11193.5 ± 115.5
Poz-18693	10.39	Pollen-enriched extract	10430 ± 50	12227 ± 197
Poz-18694	11.25	Pollen-enriched extract	11020 ± 50	12856 ± 131
Poz-18696	13.39	Pollen-enriched extract	13570 ± 70	16304 ± 251
Poz-18695	13.59	Pollen-enriched extract	14010 ± 70	16916.5 ± 288.5
Poz-19938	15.27	Pollen-enriched extract	18850 ± 130	22699.5 ± 284.5
Poz-19939	16.95	Pollen-enriched extract	24340 ± 230	28314.5 ± 455.5
Poz-18705	18.97	Pollen-enriched extract	30060 ± 240	34129 ± 414

* postbomb ages

^a Age too young because contamination from roots^b Age too old because contamination by older material from the lake margin

Table 2.

FACIES ASSOCIATION <i>(Cañellas-Boltà et al. 2012)</i>	FACIES <i>(Sáez et al. 2009)</i>	UNITS <i>(Sáez et al. 2009)</i>	Description	Paleoenvironmental interpretation
HGL	Facies 1, 2	Unit 1, bottom Unit 2	Laminated grey-reddish, muddy silt with frequent turbidite layers	High gradient lake (steep slopes of lake margins)
LGL	Facies 4, 5, 6, 7	Mid and upper Unit 2	Laminated- coloured and banded- massive brown organic mud with rare turbidite layers	Low gradient lake (gentle slope of lake margins)
SWA	Facies 8	Units 3, 4a	Reddish peat	Swamp-Mire
